Laboratory findings are also variable and, again, depend on the systems affected and the severity of injury. The packed cell volume (PCV) is often high due to dehydration, but it may be low if significant blood loss through the GIT has occurred. Total solids are often high as a result of the acute dehydration but also may be low due to renal and/or gastrointestinal protein losses or fluid shifts due to increased vascular permeability. Leukocytosis is common, but severely affected patients can be leukopenic. Thrombocytopenia is common. Nucleated red cells are often seen in blood smears as a result of thermal damage to bone marrow.

Azotemia (elevated blood urea nitrogen and creatinine levels) is a common finding and may be prerenal or renal in origin. These values can increase over 24 to 48 hours as renal failure progresses. Hypoglycemia is common early in the syndrome. Persistent hypoglycemia is associated with a poor prognosis. Liver enzymes are elevated due to direct thermal damage and hypoperfusion of the liver. Cholestasis is common. Hyperbilirubinemia is associated with a poor prognosis. Rhabdomyolysis results in increased levels of serum creatine kinase and myoglobinemia.

Blood gas and electrolyte values are variable. Respiratory alkalosis as a result of hyperventilation and metabolic acidosis as a result of shock and lactic acid production are commonly found in a mixed acid-base disorder. Sodium

and potassium levels are normal, high, or low, depending on the degree of dehydration, the severity of muscle damage, and whether vomiting and/or diarrhea is present. The onset of renal failure also affects electrolyte levels.

Urinalysis may reveal tubular cell casts, proteinuria, glucosuria in the absence of hyperglycemia, and increased urine gamma glutyl transferase (GGT), all of which indicate renal damage. Myoglobinuria indicates muscle damage and rhabdomyolysis and can exacerbate tubular necrosis.

Coagulation tests often reveal prolonged prothrombin time (PT) and activated partial thromboplastin time (aPTT). Thrombocytopenia is common. Hypofibrinogenemia and elevated levels of fibrin degradation products (FDPs) are common. Test values for D-dimer are often increased, whereas antithrombin 3 levels are decreased.

Early, aggressive treatment of heat-related signs and proactive treatment protocols directed at the complications of heatstroke reduce patient morbidity and mortality (see Figure 118-1). The most important aspect of treatment is to lower the core temperature. The pet owner should be instructed to initiate cooling measures before and during transportation. Effective cooling measures include wetting the patient with cool or tepid water and enhancing evaporation by providing air movement around the patient. It is important to note that ice water or cold water results in cutaneous vasoconstriction and loss of heat dissipation. It is also uncomfortable for the patient and can initiate the shivering reflex, resulting in heat production. More aggressive cooling techniques, such as cold water (or saline) enemas or gastric (or peritoneal) lavage with cool fluids, have not been shown to be any more effective than cool water baths and provision of air movement. Application of isopropyl alcohol has been recommended, but cutaneous vasodilatation may lead to absorption and intoxication. This measure is no longer recommended.

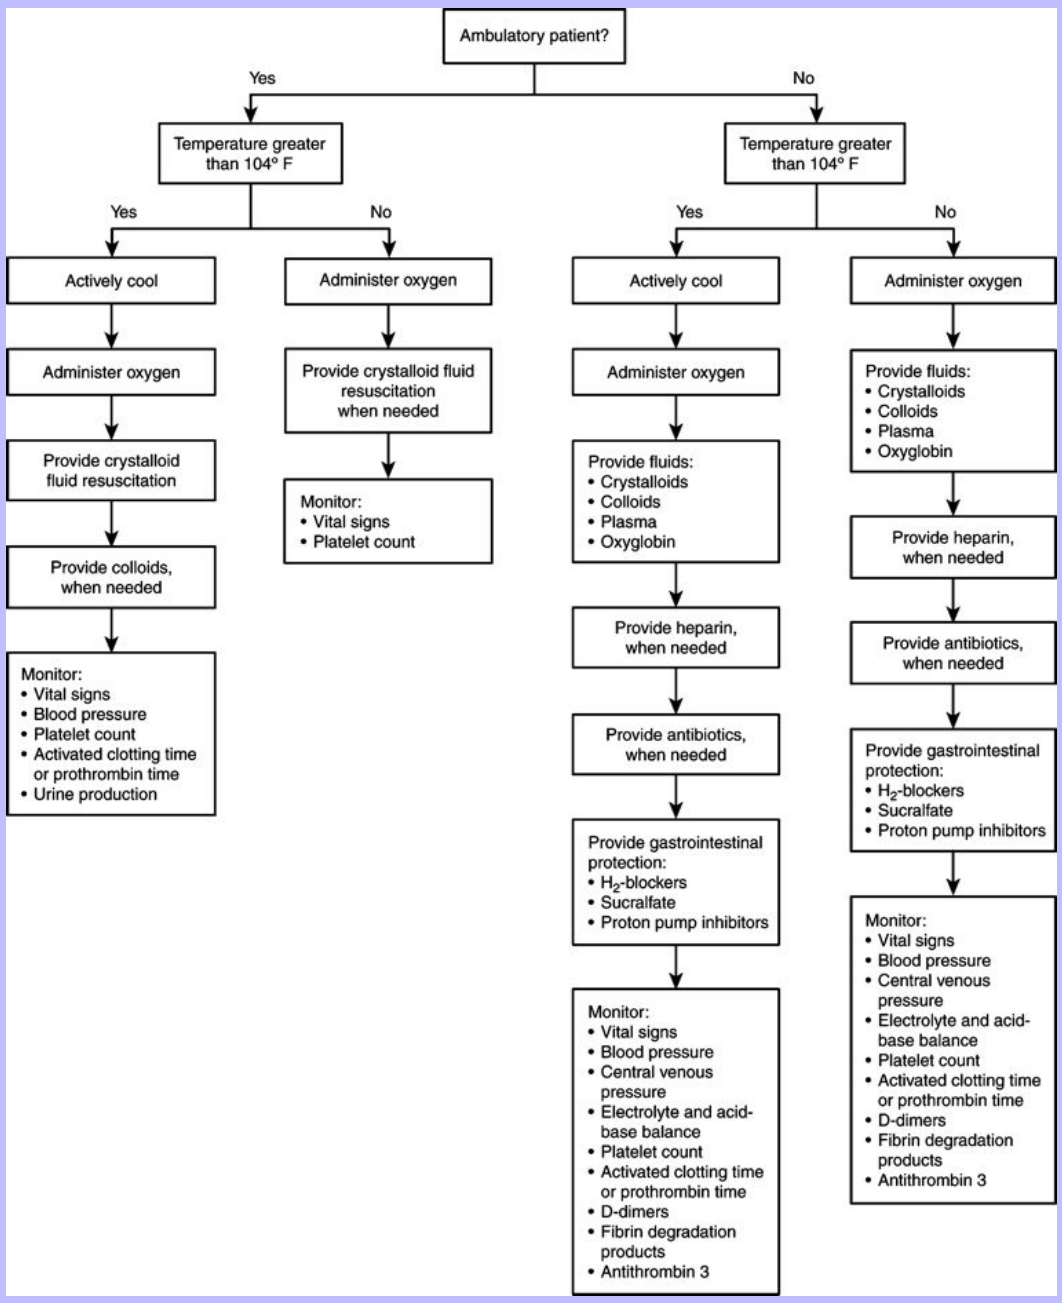
Cooling measures should continue upon arrival at the hospital if the core temperature is greater than 104°F (40°C). If the core temperature is 104°F (40°C) or lower, cooling measures must be discontinued and the patient protected from hypothermia, which increases morbidity and mortality. The patient should be given supplemental oxygen by mask, flow-by, oxygen hood, or nasal catheter.

Intravenous fluids are often required in the treatment of heatstroke, but their use must be determined on a case by case basis. Early in heatstroke or in cases of hyperthermia related to seizures, tremors, or ineffective panting, fluid imbalances are minimal, and aggressive fluid therapy can lead to volume overload. In more advanced cases of heatstroke, the patient has relative and absolute fluid losses that result in hypovolemia and perfusion deficits. These patients need aggressive fluid therapy.

Depending on the aggressiveness of fluid therapy needed, one or two catheters are implanted. In the least severe cases, crystalloid fluids (lactated Ringer's solution, Normosol-R, Plasmalyte, normal saline) are administered rapidly until perfusion parameters improve. The fluids should be room temperature. The clinician must administer “enough” fluid but not “too much.” “Enough” improves mucous membrane color, capillary refill time, blood pressure, heart rate, pulse quality, and urine production. “Too much” causes dilutional anemia, hypoproteinemia, and edema formation, particularly pulmonary edema.

438 440

Figure 118-1 Treatment of heatstroke.



In more severe cases of heatstroke, a combination of crystalloid and colloid fluids (dextrans, hetastarch, pentastarch) is recommended. Again, fluids are administered rapidly to achieve targeted end-points. When colloids are used, the volume of crystalloid can be reduced by as much as 40% to 60%. Colloids expand the intravascular volume more

effectively than crystalloids and minimize fluid loss from the increased vascular permeability that often accompanies heatstroke.

Although not approved by the U.S. Food and Drug Administration for use in heatstroke, Oxyglobin (BioPure Corp., Cambridge, Massachusetts) has been reported to be of benefit. Oxyglobin is a potent colloid that carries oxygen and is effective in improving oxygen delivery. Because many heat-stroke patients suffer decreased oxygen delivery, Oxyglobin would seem to be an effective treatment modality. The manufacturer's recommended dosage is 10 to 30 mL/kg; however, it is likely more appropriate to administer it “as needed” to achieve specific hemodynamic end-points. Anecdotal reports indicate that the dosage is often not as high as the manufacturer's recommendations.

Vasculitis, increased capillary permeability, and DIC are common in heatstroke. These conditions require the use of fresh, fresh frozen, or frozen plasma. Because early diagnosis of these conditions is difficult, experts often recommend administration of plasma and advocate a proactive treatment protocol rather than a reactive one. The author's rule of thumb is: if the patient had to be carried into the hospital, plasma should be given. The dose of plasma is variable; 10 to 20 mL/kg can be used as a guideline.

Although controversial, heparin should be considered (50 to 250 U/kg given subcutaneously every 6 to 8 hours) when plasma is administered.

Use of corticosteroids (CCS) in heatstroke is controversial. When swelling and inflammation play a role (e.g., brachycephalic syndrome), use of these drugs likely is appropriate. Although CCS are said to stabilize membranes, suppress inflammation and cytokine production, and decrease the severity of endotoxemia, as well as have antipyretic properties, they are also known to worsen gastrointestinal ulceration and ischemic damage to the kidneys. Studies of the use of CCS have shown mixed results. The use of CCS is not routinely recommended, nor is it contraindicated if other appropriate therapy has been initiated. Nonsteroidal anti-inflammatory drugs are contraindicated.

Broad-spectrum antibiotic therapy is recommended. Combinations of ampicillin, amoxicillin, cefazolin, and enrofloxacin are acceptable in most cases. Aminoglycosides may be used only after renal function has been evaluated.

Sedatives (e.g., diazepam) are given to control seizures but must be used with caution. The use of sedatives often results in hypothermia. Intravenous dextrose is necessary in hypoglycemic patients. Gastrointestinal protectant drugs, such as sucralfate, famotidine or other H_2-blockers, and/or omeprazole, are recommended if signs of GIT inflammation or ulceration are present. Intense nursing care and vigilant monitoring are essential for successful treatment of heatstroke.

119 CHAPTER • 119 Hepatic and Splenic Emergencies

David E. Holt

119.1 HEPATIC AND SPLENIC EMERGENCIES ASSOCIATED WITH HEMOPERITONEUM

Traumatic injury to the liver or spleen or rupture of splenic or hepatic masses can cause life-threatening intraperitoneal hemorrhage. Trauma to the liver and spleen is often associated with motor vehicle accidents, falls, and accidental or malicious blunt abdominal injuries, such as kicks. The most common nontraumatic cause of hemoperitoneum in dogs is rupture of splenic hemangiosarcomas. Hemorrhage from other vascular, intra-abdominal masses, including splenic hematomas and hepatic tumors, can also occur in dogs but is less common. Hemorrhage from hepatic and splenic neoplasms accounts for approximately half of feline nontraumatic hemoperitoneum cases.

Traumatized animals have often sustained severe injuries to several organs. A rapid initial examination that focuses on life-threatening injuries to the central nervous, respiratory, and cardiovascular systems should be performed. Common clinical findings in animals with traumatic hemoperitoneum include depressed mentation, pale mucous membranes, delayed capillary refill time, a rapid heart rate, and poor peripheral pulse quality. The abdomen may or may not be visibly distended. Animals with nontraumatic, bleeding splenic or hepatic masses show either acute collapse or more chronic problems, including lethargy, anorexia, weight loss, or vomiting that has acutely worsened. The physical examination findings associated with poor tissue perfusion are similar to those in animals with traumatic hemoperitoneum; however, a mass is often detected on abdominal palpation.

Intravenous (IV) access is mandatory in animals with either traumatic or nontraumatic hemoperitoneum. The veterinarian may consider placing two large-bore IV catheters. Blood samples are obtained for a minimum data base, and resuscitation can commence. The rate and type of IV fluid resuscitation is based on the assessment of the animal's perfusion deficits and the presence of concurrent injuries. Full shock doses of crystalloids (60 to 90 mL/kg/hour in the dog; 45 to 60 mL/kg/hour in the cat) or hypertonic saline and dextran (5 to 7 mL/kg given over 5 minutes) followed by crystalloids may be necessary. Fluid resuscitation should be limited in animals suspected of having pulmonary contusions (10 to 20 mL/kg given intravenously for the first hour). Temporary application of a tight abdominal bandage (abdominal counterpressure) can slow or arrest bleeding by raising intra-abdominal pressure. However, increasing intra-abdominal pressure for prolonged periods can adversely affect renal and hepatic blood flow.

The response to therapy and ongoing requirements for crystalloid or colloid fluids should be continually assessed from repeated clinical, laboratory, and monitoring (urine output, EKG, blood pressure, pulse oximeter) evaluations. Blood component therapy is often required to maintain the animal's packed cell volume (PCV) above 25%. Autotransfusion can be a lifesaving source of red blood cells in dogs or cats when fresh whole or stored blood is not available. Intra-abdominal sepsis or neoplasia is a contraindication to autotransfusion; hence, animals with no history of trauma should not be autotransfused. Peritoneal fluid is evaluated cytologically before auto-transfusion.

Hemoperitoneum may be suspected from the history and physical examination findings. A focal or generalized loss of serosal detail on abdominal radiographs indicates free peritoneal fluid. The diagnosis of hemoperitoneum should be confirmed by peritoneal fluid evaluation. A sample is obtained by abdominocentesis with or without ultrasound guidance. In animals with hemoperitoneum, the peritoneal fluid sample should not clot unless the spleen has been inadvertently aspirated. The PCV of abdominal fluid usually is greater than or equal to that of the

peripheral blood. Unfortunately, peritoneal fluid cytology is rarely helpful in diagnosing neoplastic causes of hemoperitoneum. In animals with either a palpable abdominal mass or no history of trauma, splenic neoplasia is a distinct possibility. Obvious pulmonary metastatic disease should be ruled out by evaluation of opposite lateral and dorsoventral thoracic radiographs. Abdominal ultrasonography may be useful for defining an intra-abdominal mass and for evaluation of other abdominal organs for evidence of metastatic disease.

Definitive treatment varies, depending on the underlying cause of the hemoperitoneum and the response to medical stabilization. Some dogs and cats with traumatic splenic or hepatic hemorrhage stabilize with fluid resuscitation, blood transfusion, and abdominal counterpressure. Surgery is indicated in animals with traumatic hemoperitoneum that continue to hemorrhage despite appropriate medical treatment. In humans, such circumstances would initially be investigated with interventional radiologic techniques, and obvious bleeding arteries would be embolized. These techniques are currently investigational at several veterinary schools. In animals with hemoperitoneum secondary to a bleeding splenic or hepatic mass, the aims of surgery are to stop ongoing hemorrhage, remove the mass, obtain a histopathologic diagnosis, and perform a complete exploratory to rule out gross metastatic disease. The prognosis for these animals depends on the tumor type. The two most common splenic masses in dogs are hemangiosarcoma and hematoma. Dogs have an excellent prognosis after hematoma removal; dogs with splenic hemangiosarcoma have a very guarded long-term prognosis even with chemotherapy.

119.1.1 Splenic and Liver Lobe Torsion

Although uncommon, splenic torsion should be considered in any dog with either chronic gastrointestinal (GI) signs or signs of acute abdominal disease. The pathogenesis of splenic torsion and the predisposing factors for this condition are not completely understood, but Great Danes and German shepherds are at increased risk. In many dogs, the history includes chronic signs of abdominal discomfort and GI disease, such as depression, anorexia, vomiting, and weight loss. However, some dogs with splenic torsion are initially examined as true emergency cases with signs of acute, worsening abdominal disease. The physical examination findings depend on the degree of cardiovascular instability and may include pale mucous membrane color, poor capillary refill time, and poor peripheral pulse quality. Splenomegaly may be detected on abdominal palpation in most cases and should increase the clinician's suspicion for splenic disease.

The differential diagnosis for such animals should include gastric dilatation-volvulus syndrome, GI foreign body obstruction, mesenteric torsion, peritonitis, and other causes of splenomegaly, including neoplasia. A complete blood count, serum biochemical screening, and abdominal imaging are indicated to further define the underlying disease. Radiographs show splenomegaly in all affected dogs; some can also have a loss of abdominal detail associated with peritoneal effusion or hemorrhage. Abdominal ultrasound findings of a hypoechoic pattern in the splenic parenchyma and decreased flow through the splenic veins strongly support a diagnosis of splenic torsion.

Animals should be stabilized with IV fluid resuscitation prior to induction of anesthesia. Some animals with moderate to severe anemia may require preoperative or intraoperative transfusions. Because many dogs with splenic torsion have evidence of abnormal coagulation, a coagulation screen and blood type and crossmatch are indicated prior to surgery. A protocol of balanced anesthesia with minimal cardiovascular depression should be used. Ventricular arrhythmias commonly develop intraoperatively or postoperatively, therefore electrocardiographic and blood pressure monitoring is vital. At surgery, the spleen should be removed without untwisting the splenic pedicle. Many surgeons also recommend concurrent gastropexy to prevent subsequent gastric volvulus. The prognosis is good for dogs with splenic torsion when appropriate emergency resuscitation and critical care management are combined with prompt diagnosis and surgical treatment.

Liver lobe torsion occurs rarely in dogs and cats. Clinical signs and laboratory data are nonspecific. A distended abdomen or a palpable abdominal mass can sometimes be detected on physical examination. The diagnosis is confirmed at exploratory laparotomy. The affected liver lobe should be resected either manually or with stapling equipment and submitted for histopathology.

119.1.2 Hepatic and Splenic Abscesses

Hepatic and splenic abscesses are both uncommon clinical entities in dogs but may present as true emergencies. The clinical signs and physical examination findings in dogs with these conditions are not specific. Dogs most commonly have a history of anorexia and lethargy that may be accompanied by vomiting and diarrhea. They are often febrile and have pain and hepatomegaly or splenomegaly on abdominal palpation. Occasionally, dogs with hepatic abscessation have evidence of epistaxis, ecchymosis, or hematochezia, indicating abnormal blood clotting function.

A complete blood count, serum biochemical profile, coagulation screen, and abdominal imaging studies are logical diagnostic steps in animals with these physical examination findings. Historically, all dogs with hepatic abscessation have had increased serum alkaline phosphatase (ALP) and alanine aminotransferase (ALT) activity, and the majority have a leukocytosis, thrombocytopenia, and hypoalbuminemia. The results of abdominal radiography may not be diagnostic; in one study of dogs with hepatic abscesses, most had hepatomegaly, one third had splenomegaly, and one third had a loss of abdominal detail. Abdominal ultrasound is useful in these cases and shows either hypoechoic or anechoic changes in one or more liver lobes. Samples can be obtained from affected lobes for cytology and aerobic and anaerobic culture and sensitivity testing using ultrasound guidance. If ultrasonography is not available, peritoneal lavage or exploratory laparotomy may be required to make a definitive diagnosis.

The etiology of hepatic and splenic abscesses is the subject of debate and probably is multifactorial. However, given that hematogenous bacterial spread is a potential cause, once a diagnosis has been established, possible reservoirs of bacterial infection, such as the urinary tract and heart valves, should be investigated. The animal can also then be evaluated for concurrent conditions associated with hepatic and splenic abscessation, such as biliary tract disease, diabetes mellitus, pancreatitis, neoplasia, and endogenous or exogenous glucocorticoid excess. Thoracic radiographs are indicated to rule out pneumonia; in one study, radiographic evidence of alveolar infiltrates consistent with pneumonia were found in nearly half the cases examined.

441
442

Initial stabilization in affected animals involves cardiovascular support with IV fluids and administration of broad-spectrum bactericidal antibiotics with gram-positive, gram-negative, and anaerobic coverage pending the results of culture and sensitivity tests. Bacteria cultured from canine hepatic abscesses have included *Escherichia coli, Klebsiella pneumoniae*, *Staphylococcus epidermidis*, enterococci, and clostridia. Treatment involves surgical resection of the abscessed liver lobe or lobes. In cases with diffuse hepatic involvement, percutaneous, ultrasound-guided drainage of abscesses may be appropriate. All affected animals should be treated with long-term antibiotic therapy (6 to 8 weeks). Follow-up ultrasound evaluations are recommended to monitor the response to treatment.

119.1.3 Rupture of the Biliary System

Rupture of the biliary system has been more commonly seen in dogs than cats and is usually caused by abdominal trauma or is associated with severe cholecystitis and rupture of the gallbladder. In animals with trauma-associated biliary leakage, there is usually a lag time of days to weeks between the initiating trauma and

the development of clinical signs associated with bile peritonitis. Animals with underlying cholecystitis may have chronic or intermittent clinical signs associated with the hepatic and GI systems. Once the biliary tract begins to leak substantially, clinical signs of peritonitis develop, prompting owners to seek veterinary attention.

Clinical signs vary in severity, depending on the extent of the peritonitis (local or general) and whether secondary bacterial infection of the bile and peritoneal fluid is a factor. Clinical signs may include lethargy, anorexia, vomiting, and diarrhea. On physical examination, the mucous membranes may be icteric; parameters indicating perfusion, such as the capillary refill time, heart rate, and pulse quality, are variably altered, depending on the severity of the peritonitis. The abdomen is often distended and painful. Plain abdominal radiographs show a local or generalized loss of abdominal detail. In cases of necrotic cholecystitis, choleliths and/or free gas may be visible in the cranial abdominal quadrant. Blood work often shows a leukocytosis and an increase in the serum bilirubin concentration and ALP and ALT activity. A diagnosis of bile leakage potentially can be made from analysis of peritoneal fluid samples. The finding of free bile crystals on cytology or a peritoneal fluid bilirubin level higher than that of serum should prompt exploratory surgery.

Prior to surgery, the animal is rapidly and aggressively stabilized with IV crystalloids and possibly colloids. Broad-spectrum bactericidal antibiotics are administered, because bile peritonitis often involves gram-negative bacterial contamination. A preoperative coagulation screen is mandatory in these cases, because the absence of bile salts in the duodenum and jejunum precludes absorption of fat and fat-soluble vitamins such as vitamin K. Fresh frozen plasma is required to prevent excessive surgical hemorrhage secondary to lack of coagulation factors. Vitamin K supplementation should be given immediately (1 to 2 mg/kg subcutaneously). In cases of traumatic biliary leakage, the biliary system is directly repaired or bile is diverted by means of a cholecystoenterostomy. In cases of gallbladder rupture secondary to cholecystitis, a cholecystectomy is performed. Samples are taken from the liver and peritoneal cavity for bacterial culture and sensitivity testing. The liver is biopsied. The peritoneal cavity is copiously lavaged with sterile isotonic fluid and either closed or left open. (Chapter 43 presents a more detailed description of the management of peritonitis.)

119.1.4 Acute Hepatic Failure

Peracute hepatic failure has many potential causes in small animals, including chemical agents; biotoxins; anesthetics and other drugs; viral, bacterial, and other infectious agents; neoplasia; copper storage disease; and hepatic lipidosis in cats. Hepatic failure is diagnosed in humans that have hepatic encephalopathy (HE) and a concurrent coagulopathy. Hepatic encephalopathy is a complex syndrome of neurologic alterations seen in association with moderate to severe liver disease. The cause of the neurologic signs seen in HE is multi-factorial; elevations in serum and central nervous system (CNS) ammonia levels alter the glutamate, gamma amino butyric acid, and serotonin neurotransmitter systems. Changes in the central and peripheral benzodiazepine receptor systems also occur. Small animals often have clinical signs of weakness, depression, collapse, anorexia, vomiting, and diarrhea. Physical examination findings are rarely specific; signs of spontaneous hemorrhage, including ecchymosis, icterus, and cranial organomegaly, increase suspicion for liver disease but do not differentiate between an acute hemolytic crisis and extrahepatic biliary obstruction. Owners should be questioned carefully about possible drug or toxin exposures.

A diagnosis may be suspected from the history and physical examination findings and the results of serum biochemical and liver function tests, including a coagulation profile. Abdominal ultrasonography may be helpful for visualizing the liver and obtaining either aspirates or biopsy specimens for cytology, culture, and histopathology. Treatment is largely supportive and involves cardiovascular support with crystalloid and colloid fluids, correction of electrolyte and acid-base imbalances, reduction of serum ammonia levels, and treatment of any seizurelike activity. The clinician should pay particular attention to hypokalemia and alkalosis, because both of these conditions increase ammonia uptake to the CNS. Serum ammonia is lowered by administering

lactulose, a nondigestible disaccharide that acidifies the colon, decreasing ammonia production and converting ammonia into nonabsorbable ammonium ions. In comatose animals, lactulose is administered as an enema (10 to 80 mL). In some instances administration of flumazenil, a benzodiazepine receptor antagonist (0.02 mg/kg given intravenously), is helpful. In animals with HE and seizure-like activity, propofol is administered as a bolus (0.5 1 mg/kg given intravenously) and then as an infusion (0.05 to 0.1 mg/kg/minute given intravenously).

120 CHAPTER • 120 Pulmonary Emergencies

Fred A. Mann

Exacerbation of any pulmonary disease can result in life-threatening hypoxia requiring emergency treatment. Pulmonary emergencies that occur as a direct result of acute injury or disease in previously normal lungs include pulmonary edema, pulmonary contusion, aspiration pneumonia/pneumonitis, smoke inhalation, near-drowning, pulmonary thromboembolism, and acute lung injury/acute respiratory distress syndrome.

120.1 PULMONARY EDEMA

Pulmonary edema is the accumulation of fluid in the pulmonary interstitium and alveoli due to imbalance among the six interstitial fluid control factors: (1) capillary hydrostatic pressure, (2) capillary oncotic pressure, (3) interstitial hydrostatic pressure, (4) interstitial oncotic pressure, (5) capillary wall integrity, and (6) pulmonary lymphatic function (Figure 120-1).

Cardiogenic pulmonary edema is due to increased capillary hydrostatic pressure induced by congestive heart failure. Noncardiogenic pulmonary edema may result from alterations in any one or more of the interstitial fluid control factors, including capillary hydrostatic pressure. Examples of conditions that can cause noncardiogenic pulmonary edema include head injury, seizures, and electrical shock, all of which have unknown mechanisms but seem to involve both increased capillary hydrostatic pressure and increased capillary permeability; smoke inhalation, near-drowning, aspiration pneumonia/pneumonitis, acute lung injury/acute respiratory distress syndrome, uremia, pancreatitis, and toxins, all of which are thought to involve altered capillary permeability; liver disease, protein-losing enteropathy, protein-losing nephropathy, and burns, all of which are characterized by hypoproteinemia and decreased capillary oncotic pressure but may involve other interstitial fluid control factors; infiltrative pulmonary neoplasia, which may result in pulmonary edema due to lymphatic obstruction; postobstruction pulmonary edema; and re-expansion pulmonary edema. Postobstruction pulmonary edema occurs when correction of airway obstruction results in loss of intrinsic positive end-expiratory pressure (PEEP). Exhalation against an obstruction creates a PEEP that is suddenly gone when the obstruction is relieved, resulting in interstitial and alveolar flooding. Re-expansion pulmonary edema occurs when atelectatic lungs are rapidly re-inflated through (manual or mechanical) positive pressure ventilation. The rapidity of reinflation, not the chronicity of the atelectasis, is the cause. Re-expansion pulmonary edema is thought to be a form of increased-permeability pulmonary edema arising from hypoxic injury to capillary and alveolar membranes followed by a rapid increase in capillary hydrostatic pressure during re-expansion.

Pulmonary edema is life-threatening because it impairs pulmonary compliance, vital capacity, and pulmonary gas exchange. Treatment is directed at the underlying cause but also includes oxygen administration and the use of bronchodilators and diuretics. Failure of oxygen and medical therapy to resolve hypoxemia necessitates ventilation therapy and PEEP. Monitoring of pulmonary edema involves thoracic radiography; however, clinical signs may precede, and pulmonary recovery may lag behind, the radiographic appearance.

120.2 PULMONARY CONTUSION

Pulmonary contusion, the accumulation of hemorrhage in lung parenchyma as a result of traumatic injury, can cause fatal pulmonary impairment. Fortunately, most pulmonary contusions are self-limiting and respond to supportive treatment with oxygen administration, rest, and judicious fluid therapy. Fluid overload is a concern because many pulmonary contusion patients are in shock and require intravascular volume expansion. Overzealous

fluid administration for resuscitation may be avoided by using hypertonic saline (4 to 5 mL/kg given intravenously) followed by isotonic crystalloids to achieve targeted perfusion parameters. Diuretic therapy may be required to treat fluid overload. Antibiotics are not indicated for treatment of pulmonary contusions. If the patient remains hypoxic on supportive treatment, ventilation therapy with PEEP is required.

Because pulmonary contusions can worsen over 48 to 72 hours, they require close monitoring, and in some cases, therapeutic interventions for concurrent injuries must be postponed. Thoracic radiographs are used to monitor the progression and resolution of pulmonary contusions, but the radiographic appearance may not correlate with the clinical signs and the ability of the injured lungs to accommodate another insult, such as anesthesia. Radiographic resolution may precede full recovery of pulmonary function.

120.3 ASPIRATION PNEUMONIA AND PNEUMONITIS

Pneumonia and *pneumonitis* are characterized by the accumulation of inflammatory fluid in the pulmonary interstitium and alveoli (Figure 120-2). Emergent onset of pneumonia or pneumonitis occurs as a result of aspiration. If an infectious substance, such as oropharyngeal bacteria, is aspirated, the inflammatory condition is referred to as *aspiration pneumonia*. If acidic stomach contents are aspirated, a noninfectious, chemical-induced inflammation, referred to as *aspiration pneumonitis,* may occur. It is important to distinguish between pneumonia and pneumonitis because of important differences in therapy. Antibiotic therapy is not indicated, at least initially, with aspiration pneumonitis because the antibiotic may select for resistant organisms. Conversely, antibiotics should be promptly administered in cases of aspiration pneumonia after a transtracheal wash sample has been obtained for culture and susceptibility testing. Lungs with aspiration pneumonitis experience oxygen toxicity at typically safe levels of oxygen administration and therefore can be harmed by excessive oxygen, whereas lungs with aspiration pneumonia may benefit from standard oxygen therapy. If pneumonitis is suspected, the lowest inspired oxygen concentration that maintains normal hemoglobin saturation is used.

443

445

Figure 120-1 Causes of pulmonary edema.

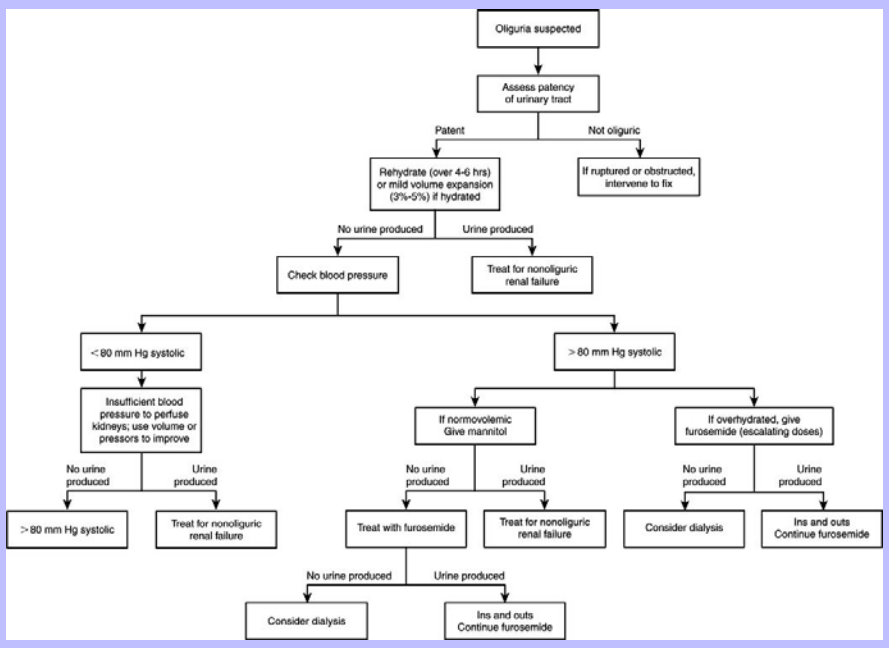

Figure 120-2 Differentiation of aspiration pneumonia and pneumonitis. *Note:* Because of the difficulty in clinical differentation, treatment strategy is based on whether the aspiration event is witnessed.

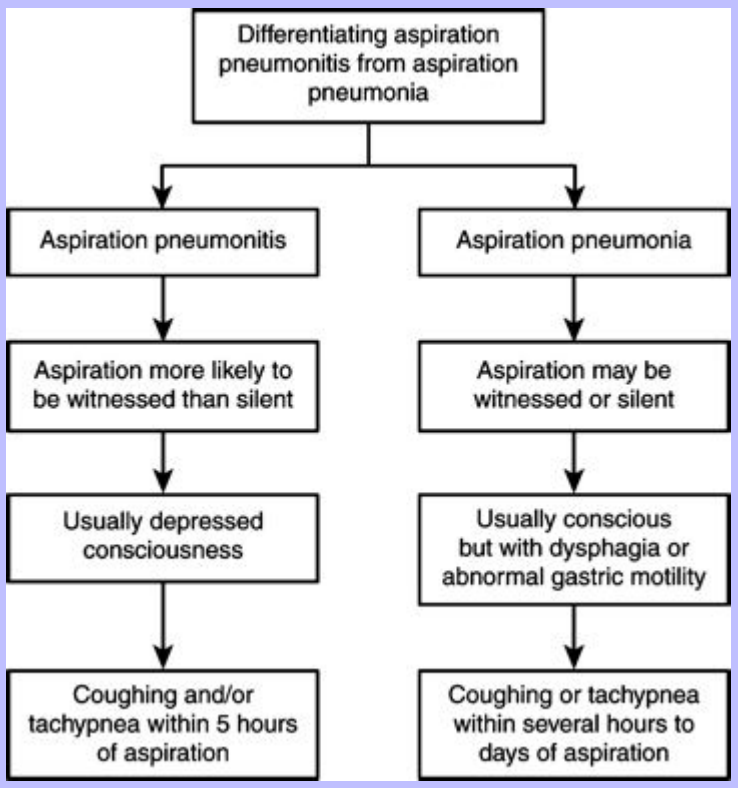


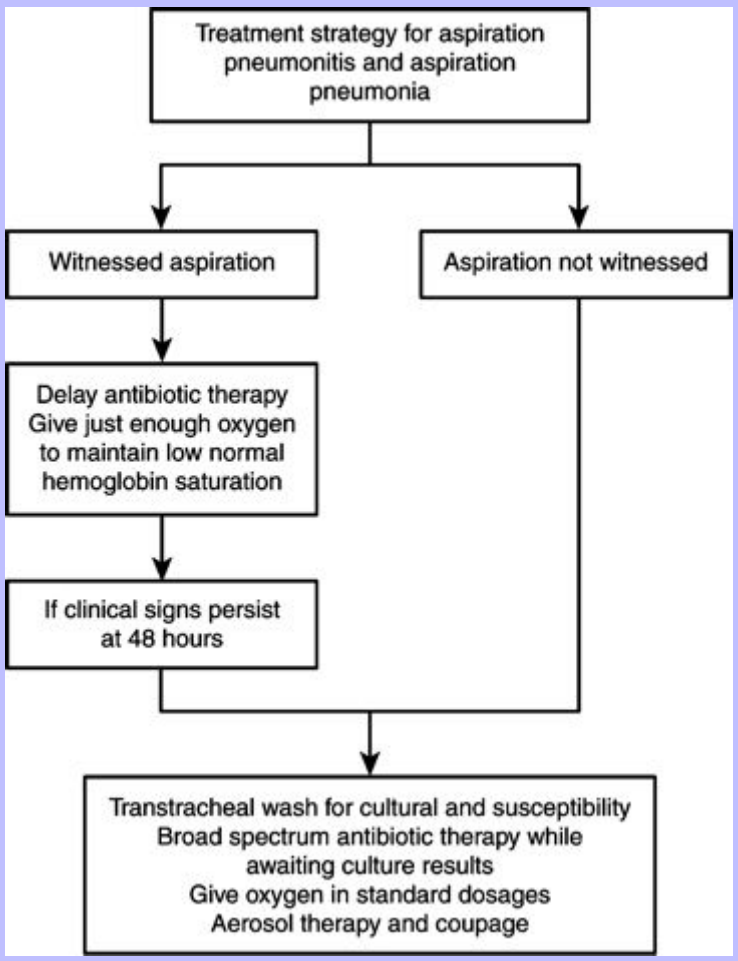
Unfortunately, the differentiation between pneumonitis and pneumonia is not straightforward. Both types of aspiration may be witnessed or silent, but aspiration pneumonitis is more likely if the aspiration event is witnessed. Pneumonitis is more common in patients with depressed consciousness, whereas pneumonia is more common in patients with dysphagia and/or gastric motility disorders. Clinical signs may be absent in both, but when they occur, the onset may differ. Coughing and/or tachypnea typically occur within 5 hours of aspiration in pneumonitis, but they occur later (several hours to days) in pneumonia, depending on how long it takes the aspirated bacteria to reach pathogenic numbers.

Because of the difficulty in differentiation, the following therapeutic approach is recommended (Figure 120-3):

- *If the aspiration event is witnessed:* Antibiotic therapy is delayed, and just enough oxygen is administered to maintain normal oxygen saturation of hemoglobin. Antioxidant therapy, such as administration of vitamin E, may also be beneficial. If clinical signs fail to resolve within 48 hours, broad-spectrum antibiotic therapy is begun, preferably after transtracheal wash samples have been obtained.
- *If the aspiration event is not witnessed:* A transtracheal wash is performed, and broad-spectrum antibiotic therapy is pursued until culture and susceptibility results become available. Standard doses of oxygen are

administered to maintain normal oxygen saturation of hemoglobin. With pneumonia, aerosol therapy and coupage may be used to facilitate both delivery of antibiotics to the respiratory tree and elimination of excessive respiratory secretions.

Figure 120-3 Treatment strategy for aspiration pneumonitis and pneumonia.



120.4 SMOKE INHALATION

Thermal injury from inhaled smoke is typically limited to the airways, but carbon monoxide and other toxic substances in smoke may cause pulmonary injury and dysfunction. Carbon monoxide binds with great affinity to hemoglobin, and the resultant carboxyhemoglobin is unable to carry oxygen. Administration of 100% oxygen shortens the half-life of carboxyhemoglobin from 4 hours to 30 minutes. As such, the most important treatment for smoke inhalation is early, preferably at the scene, oxygen therapy. Toxic substances may injure the lungs to the point of pulmonary edema, necessitating diuretics, careful fluid therapy, continued oxygen, and supportive care. Fluid therapy cannot be avoided, particularly if concurrent burns are a factor, but fluid rates must be monitored closely, preferably incorporating central venous pressure monitoring, to avoid fluid overload. The prognosis for

smoke inhalation injury is good if no signs of pulmonary impairment are present on the day of admission. The prognosis is also good for patients with signs of respiratory dysfunction upon admission if the signs do not worsen the day after admission.

120.5 NEAR-DROWNING

The ultimate concern in near-drowning is hypoxic brain injury. In the lungs, abnormalities of gas exchange may occur as a result of (1) fluid aspiration and destruction of surfactant, (2) disruption of alveoli and capillaries, and/or (3) pulmonary hypertension, all of which contribute to the development of pulmonary edema. The most successful near-drowning cases are those in which immediate reversal of hypoxia is achieved, before permanent neurologic impairment ensues. Immediate resuscitation provides the best possible outcome; however, first-responder cardiopulmonary-cerebral resuscitation at the scene is not widely available in veterinary medicine. Once the resuscitated near-drowning victim reaches the hospital, priorities are given to maintaining normoxemia, treating pulmonary edema, assessing neurologic function, and providing neurologic support therapies.

445
446

120.6 PULMONARY THROMBOEMBOLISM

Pulmonary thromboembolism (PTE) is rarely diagnosed ante mortem and is probably responsible for many acute unexpected deaths. Clinical diagnosis of PTE is based on unexplainable dyspnea concurrent with normal thoracic radiographs or thoracic radiographs with hypovascular lung regions or alveolar infiltrates that do not correlate with the degree of respiratory distress. The diagnosis is supported by known risk factors, such as dirofilariasis, nephrotic syndrome, immune-mediated hemolytic anemia, hyperadrenocorticism, pancreatitis, sepsis, neoplasia, and any condition that sets the stage for Virchow's triad: (1) hypercoagulable state, (2) vascular stasis, and (3) disruption of vascular endothelium.

Treatment for pulmonary thromboembolism includes symptomatic respiratory support and anticoagulant therapy. Rarely is thrombolytic therapy used. Most commonly, the patient is heparinized. A baseline activated partial thromboplastin time (aPTT), prothrombin time (PT), and activated clotting time (ACT) are obtained, and an initial intravenous dose of heparin (200 U/kg) is given, followed by 100 to 200 U/kg given subcutaneously or intravenously every 6 hours. The actual repeat doses are often even lower and are based on maintenance of the aPTT at one and one half to two times normal. The ACT can be used to adjust doses such that it is prolonged to 15 to 20 seconds over baseline; however, the aPTT should be monitored at least once daily. Heparin therapy may be slowly discontinued if the inciting cause is reversed. If prolonged anticoagulant therapy is needed, Warfarin may be given per os at a dosage of 0.2 mg/kg once, followed by 0.05 to 0.1 mg/kg to achieve a PT of one and one half to two times normal. Warfarin must be started before heparin is discontinued because Warfarin may be thrombogenic initially.

120.7 ACUTE LUNG INJURY AND ACUTE RESPIRATORY DISTRESS SYNDROME

Acute lung injury (ALI) and acute respiratory distress syndrome (ARDS) are severe conditions that result from direct lung insult, such as pulmonary contusion, pneumonia, smoke inhalation, near-drowning, and oxygen toxicity, or from indirect lung injury associated with sepsis, systemic inflammatory response syndrome, shock, pancreatitis, parvoviral enteritis, organ torsion, and some toxicities. Differentiation of ALI from ARDS is based on the severity of hypoxemia; the ratio of the partial pressure of arterial oxygen to the fraction of inspired oxygen (PaO_2:FIO_2) in ALI is 200 to 300, whereas the ratio for ARDS is less than 200. All ARDS cases result from progression of ALI, but not all ALI cases lead to ARDS. The hallmark of ALI/ARDS is hypoxemia refractory to increasing amounts of oxygen.

In ALI/ARDS, direct or indirect injury to pulmonary vascular endothelium and/or alveolar epithelium results in local inflammation that for unknown reasons spreads to the entire pulmonary system. Edema worsens. Flooded alveoli are perfused but cannot be ventilated; therefore, refractory hypoxemia results. Edema leads to decreased functional residual capacity, airway closure, atelectasis, decreased compliance, and increased work of breathing. Clinical signs, which are usually seen within 24 hours of the inciting cause, include dyspnea (which may be the only sign in early stages), tachypnea, increased abdominal effort, crackles, and harsh lung sounds. Hypotension and fever may also be present. The most common radiographic finding is diffuse alveolar infiltrates with normal cardiac silhouette and pulmonary vasculature. The diagnosis is supported by the presence of hypoxemia and alveolar infiltrates in the absence of congestive heart failure.

Treatment of ALI/ARDS consists of identification and treatment of the underlying cause and maintenance of adequate oxygen delivery to tissues. Tissue oxygenation is promoted by treatment or avoidance of edema, hypotension, volume overload, infection, and oxygen toxicity. Supplemental oxygen is given to maintain the arterial hemoglobin saturation above 90% and the PaO_2 above 60 mm Hg, to decrease the work of breathing, and to decrease the myocardial workload. Oxygen supplementation at an FIO_2 of less than 0.5 is administered to avoid oxygen toxicity. If a higher FIO_2 is necessary after 8 hours of supplementation, ventilation therapy with PEEP is warranted. Strict fluid balance, usually with a combination of crystalloids and colloids, is necessary to ensure tissue perfusion while avoiding fluid overload, because most deaths are the result of secondary organ failure rather than the pulmonary disease. Likewise, supportive management should include monitoring of blood pressure, coagulation, hemoglobin content, renal function, and nutrition, and appropriate therapeutic intervention when needed.

121 CHAPTER • 121 Renal Emergencies

Cathy E. Langston

Immediate care is required for a dog or cat that is not excreting an adequate amount of urine (i.e., 1 to 2 mL/kg/hour). The patency of the urinary tract should be evaluated for obstruction or rupture. To restore adequate urine flow, the structural problem must be alleviated or bypassed (Figure 121-1).

Insufficient blood flow to the kidney from prerenal causes can substantially decrease the glomerular filtration rate (GFR). Long-standing ischemia may also lead to intrinsic renal failure. A wide variety of factors can cause acute intrinsic renal failure (ARF), which may exist as oligoanuria (less than 0.25 mL/kg/hour), nonoliguria (0.25 to 2 mL/kg/hour), or polyuria (greater than 2 mL/kg/hour). Dogs and cats with chronic renal failure may have a decompensated uremic crisis, which initially should be managed as nonoliguric acute renal failure.

The pet may have a known history of potential renal insult (e.g., ingestion of a nephrotoxic drug or antifreeze, a recent ischemic event), or it may have signs suggestive of ARF (recent onset of polyuria and polydipsia, vomiting, and anorexia). The physical examination may reveal renomegaly, pain, uremic ulcers, or halitosis.

In the initial stages of ethylene glycol intoxication (30 minutes to 12 hours after ingestion), clinical signs may include central nervous system (CNS) depression, incoordination, ataxia, somnolence, seizures, and coma. Hypothermia and vomiting are also common. Marked polydipsia occurs in dogs, and both dogs and cats initially become polyuric. These signs may resolve, to be followed by signs of ARF after 24 to 72 hours in dogs and as early as 12 hours in cats.

With leptospirosis, clinical signs commonly encountered include fever, musculoskeletal pain, severe and persistent vomiting and diarrhea, oculonasal discharge, hemorrhagic diathesis, peripheral lymphadenopathy, and dyspnea. The presence of icterus in an animal with ARF is suggestive of leptospirosis, although not all serovars are associated with hepatic involvement. Leptospirosis is a zoonotic disease, and appropriate precautions should be taken when handling any dog suspected of having the disease.

Test results consistent with ARF include an increased anion gap, metabolic acidosis, hypocalcemia, or hyperkalemia. Ethylene glycol toxicity may cause hyperglycemia. In addition to isosthenuria, urinalysis may reveal proteinuria, glucosuria, hematuria, pyuria, or cylindruria. Oxalate crystals may be present with ethylene glycol toxicity.

Abdominal radiographs typically show either normal or enlarged kidneys; the contours should be smooth with ARF. With ethylene glycol toxicity, the kidneys may appear more radiopaque than surrounding soft tissue structures. Abdominal ultrasonography usually shows normal to enlarged kidneys with normal architecture. Ethylene glycol toxicity frequently results in hyperechoic cortices compared with the liver. Thoracic radiographs may show an interstitial pattern with leptospirosis or an interstitial to alveolar pattern if volume overload has led to pulmonary edema.

A serum chemistry panel documents azotemia and hyperphosphatemia. Liver enzyme activity may be increased in leptospirosis, with peak liver involvement occurring about 6 to 8 days after the onset of renal involvement. Changes in the complete blood count are usually nonspecific. Dogs with leptospirosis may have a mild, nonregenerative anemia, leukocytosis, or thrombocytopenia. Urine culture may demonstrate bacterial growth in animals with bacterial pyelonephritis.

Specific tests available for ARF include an ethylene glycol test to confirm exposure. However, because of the limits of detection of the test, cats can have nephrotoxic ethylene glycol concentrations and yet produce a negative test

result. The test result may be negative in both dogs and cats 12 hours after ingestion as a result of metabolism of ethylene glycol. Leptospirosis serology is not available on an emergency basis.

Fluid therapy is one of the first considerations for treatment of renal emergencies. Rehydration should take place over 4 to 24 hours, depending on the animal's cardiovascular status. Most ARF patients should be rehydrated over a short time (4 to 6 hours). If the animal is hydrated, a fluid volume equal to 3% to 5% of body weight should be administered to account for clinically undetectable dehydration. Urine output should be assessed after rehydration, and fluid therapy should be tailored to fluid output (ins-and-outs). Administered fluid should be at a base rate equaling insensible loss (22 mL/kg/day) plus the volume of sensible loss (urine production) over the previous time period. If vomiting is profuse, an estimate of this volume is added to measurements of urine output. This method is appropriate both for oliguric/anuric animals, to avoid overhydration, and for polyuric dogs and cats, in which the volume of urine frequently exceeds the clinician's estimate. Plasma or colloids (e.g., hetastarch, dextran) may be indicated.

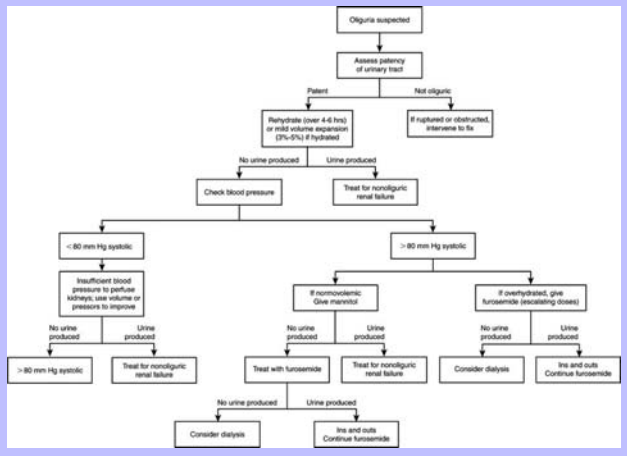
If urine output remains low (less than 0.25 mL/kg/hour) in a hydrated animal with a blood pressure adequate to perfuse the kidneys (mean arterial pressure [MAP] greater than 80 mm Hg), diuretics are indicated. Mannitol (0.5 g/kg given intravenously over 20 minutes) is an osmotic diuretic but is contraindicated in dehydrated or overhydrated animals. Furosemide, a loop diuretic, may induce urine flow within 20 to 30 minutes after an initial intravenous bolus of 2.2 mg/kg. If this does not occur, the dose can be doubled, up to 10 mg/kg. Higher doses may lead to ototoxicity. Furosemide and mannitol can be given together. Use of dopamine as a diuretic is controversial, although it is useful at higher doses as a pressor agent for hypotensive patients.

Treatment of metabolic acidosis is recommended when the serum pH is below 7.2 or the serum bicarbonate concentration is less then 16 mEq/L. Sodium bicarbonate should be dosed according to the following formula:

$$\text{Body weight (kg)} \times 0.3 \times (20 - \text{Patient's bicarbonate concentration})$$

One quarter to one third of the dose is administered over 10 to 20 minutes, and an additional $1_{/4}$ to $1_{/3}$ of the dose is administered over the next 4 to 8 hours. Rapid administration, excessive dosing, or administration to an animal with impaired respiratory function can lead to paradoxical CNS acidosis.

Figure 121-1 Algorithm for the management of a dog or cat suspected of having oliguric or anuric acute renal failure.



Hyperkalemia may cause cardiac or ECG abnormalities, characterized by bradycardia; wide, flattened, or absent P waves; peaked T waves; wide QRS complexes; atrial standstill; idioventricular rhythm; ventricular fibrillation; or asystole. Regular insulin (0.1 to 0.25 U/kg given intravenously) with dextrose to prevent hypoglycemia (1 to 2 g/unit of insulin as an intravenous bolus, followed by 1 to 2 g/unit over the next 4 to 8 hours) or bicarbonate (0.5 to 2 mEq/kg given intravenously) temporarily shifts potassium intracellularly, with an effect occurring within about 20 to 30 minutes. If a more immediate effect is needed, 10% calcium gluconate (0.5 to 1.0 mL/kg) can be administered as a slow intravenous bolus for its cardioprotective effect, although it does not decrease plasma potassium concentrations. These emergency treatments must be followed by procedures that remove potassium from the body (i.e., induction of urine flow or dialysis).

Uremia may induce gastritis or gastric ulceration. Histamine (H_2 receptor) blockers are commonly used to treat gastritis. They include famotidine (0.5 to 1 mg/kg given intravenously every 24 hours), ranitidine (2.2 mg/kg given intravenously every 24 hours), or cimetidine (2.5 to 5 mg/kg given intravenously every 12 hours). Because renal excretion of ranitidine and cimetidine is significant, this is a reduced dose. Sucralfate (0.25 to 1 g given orally every 6 to 8 hours) aids healing of uremic ulcers. It should be given at least 30 to 60 minutes before oral antacids. Uremic toxins can induce nausea by stimulating the chemoreceptor trigger zone. Metoclopramide (0.2 to 0.5 mg/kg given intravenously or intramuscularly every 6 to 8 hours, or 0.25 to 0.5 mg/kg/day given intravenously as a constant-rate infusion) is a centrally acting antiemetic. It is also a dopamine receptor antagonist and should not be administered concurrently with dopamine. Other antiemetics, such as chlorpromazine, can cause hypotension if the animal is not adequately hydrated. Little information is available on the use of 5-HT_3 serotonin receptor antagonists (e.g., ondansetron or dolasetron) in the treatment of vomiting associated with renal failure in animals.

Hyperphosphatemia is common in both acute and chronic renal failure as a result of decreased renal excretion. An acute increase in the phosphate concentration causes a compensatory decrease in the calcium concentration. Because the ionized calcium concentration is usually maintained within normal limits, signs of hypocalcemia tetany are infrequently observed. Oral phosphate binders (e.g., aluminum hydroxide) should be used once vomiting has been controlled and the animal is being fed enterally.

Respiratory compromise from pleural effusion caused by volume overload may require thoracocentesis. No effective method of addressing pulmonary edema exists in anuric animals other than ultrafiltration by means of dialysis. Careful attention to fluid therapy and urine output is crucial to avoid this complication.

Hypertension may accompany either acute or chronic renal failure, and excessive volume expansion (particularly in the face of oliguria or anuria) can exacerbate the condition. Therapy may not be necessary if the hypertension is mild and renal failure is resolving rapidly. However, in more severe cases emergency therapy may be necessary to prevent catastrophic effects.

Anorexia is common with acute renal failure. Because of the highly catabolic state associated with ARF, nutritional support should be started early in the course of the illness. If vomiting can be adequately controlled pharmacologically, enteral feeding with a feeding tube should be started. If enteral feeding is not possible, partial or total parenteral nutrition should be instituted. Calories should be predominantly carbohydrates, with restricted protein content. Ideally, protein should be supplied as essential amino acids.

Uremia induces a thrombocytopathy, and the risk of bleeding should be considered when invasive procedures are planned (e.g., renal biopsy, feeding tube placement). Because coagulation parameters and platelet numbers may be normal, a buccal mucosal bleeding time is the preferred method of assessment.

For ethylene glycol toxicity, specific antidotes are indicated. Four-methylpyrazole (4-MP (fomipezole); Antizol-Vet, Orphan Medical, Minnetonka, Minnesota) is effective in dogs if given within 8 hours of ingestion. Standard doses are not effective in cats. Dosing for dogs is 20 mg/kg initially, given intravenously, then 15 mg/kg at 12 and 24 hours, and 5 mg/kg at 36 hours. If 4-MP is not available, 20% ethanol can be used to competitively inhibit alcohol dehydrogenase. A dose of 5.5 mL/kg every 4 hours for five treatments, then every 6 hours for four treatments, can be given as an intermittent intravenous bolus but is better administered as a constant-rate infusion. In cats, 20% ethanol can be dosed at 5 mL/kg every 6 hours for five treatments, then every 8 hours for four treatments. Drinking alcohol (50% ethanol [100 proof]) can be diluted with saline. Respiratory depression can be profound with alcohol. Neither 4-MP nor alcohol is effective if started more than 8 hours after toxic ingestion.

Antibiotics should be administered if leptospirosis or pyelonephritis is suspected or documented. High doses of penicillin are effective at clearing leptospiremia. Doxycycline (2.5 mg/kg PO or IV every 12 hours) is effective at clearing leptospiremia and possibly leptospiuria. The most common cause of bacterial pyelonephritis is *Escherichia coli* infection. Empirically used antibiotics should have a good gram-negative spectrum and should not be nephrotoxic.

Adequate monitoring of animals with acute renal failure is essential. They are acutely and severely ill. Their status can change rapidly and dramatically. Urine output should be monitored in all animals with renal failure. This is most accurately accomplished with an indwelling urinary catheter with a closed collection system. Changes in body weight over the course of hospitalization primarily reflect changes in body water content and hydration. Other parameters (e.g., blood pressure, central venous pressure, packed cell volume) should be monitored as needed.

If conventional medical management fails to induce diuresis in an oliguric or anuric dog or cat, if life-threatening complications are present (i.e., hyperkalemia, volume overload), or if azotemia fails to improve after 24 hours of therapy, dialytic therapy (either hemodialysis or peritoneal dialysis) should be considered. (see Figure 121-1.)

The outcome of acute renal failure is poor. Approximately 60% of dogs and cats die or must be euthanized. Renal trauma may require emergency surgery to control massive hemorrhage.

122 CHAPTER • 122 Gynecologic Emergencies

Saralyn Smith-Carr

Most gynecologic emergencies occur during the periparturient, diestrus, or postestrus periods. It is the responsibility of the veterinarian to act quickly to ensure preservation of the life of the bitch, the neonate and future reproductive potential of the bitch (in that order). The reasons owners seek veterinary assistance for reproductive emergencies are listed in Table 122-1. A complete breeding history should always be obtained along with a thorough physical examination. Details of each reproductive disorder have been reviewed elsewhere.

122.1 DYSTOCIA

Dystocia is the inability of the female to expel the fetus through the birth canal at parturition. The bitch's body temperature drops below normal (<100°F), 8 to 24 hours before the onset of labor, due to serum progesterone, decreasing to less than 2 ng/dl. There are three stages of labor. During the first stage, the bitch may become anxious, restless, or seek seclusion. There are no obvious uterine contractions but cervical dilation occurs and clear vaginal fluid discharge may be seen, which indicate chorioallantois membrane rupture. During stage II labor there are noticeable abdominal contractions, fetal membranes are visualized at the vulva, and the puppy or kitten is immediately expelled. Delivery of the first newborn usually occurs within 20 to 30 minutes of the onset of stage II labor. Stage III labor is a resting period, during which the placental membranes are passed and the bitch cares for the neonate. Causes of dystocia may be maternal or fetal in origin. Specific details on maternal and fetal causes of dystocia have been reviewed elsewhere.

Table • 122-1 Reasons for Seeking Veterinary Assistance for Reproductive Disorders

PRESENTING COMPLAINT	DISORDER(S)
No signs of labor at >24 hours after temperature decrease to <100°F More than 1 week overdue Fetal membranes in vulva >15 minutes Strong contractions >30 minutes without delivery	Normal or dystocia
No fetus produced after 4–6 hours of onset of stage II labor	Dystocia
More than 3 hours between fetal delivery	Dystocia in canine
Vaginal discharge	Dystocia, metritis, pyometra
Temperature >103.5°F in the bitch Profuse vomiting, diarrhea and toxemia in bitch Incessant crying of offspring	Dystocia, metritis, pyometra, uterine torsion, mastitis
Anorexia, lethargy, depression >24 hours postpartum	Metritis, mastitis
Hot, painful, swollen mammary glands	Mastitis
Extreme restlessness, panting, tremors, and stiff gait	Eclampsia

Regardless of the origin of dystocia, maternal or fetal, either primary or secondary uterine inertia occurs and the owner seeks veterinary assistance. After taking a history, a general physical examination should be performed to determine the degree of maternal compromise. Next, detailed examination of the reproductive tract should be performed beginning with visual inspection of the vulva for presence of discharge, fetal membranes, or fetal parts. Mucoid or greenish black (lochia) vaginal discharge are normal findings but may indicate obstruction if present for more than 2 hours without delivery. Sanguineous or bloody vaginal discharge may indicate vaginal trauma or uterine torsion. Reddish brown fetid discharge indicates fetal death and subsequent metritis.

Presence of fetal membranes or fetal parts should prompt digital examination of the vagina and/or rectum to palpate for any obstruction. Abdominal palpation should be performed to ascertain fetal presence and discern fetal movement. Auscultation of the abdomen for fetal heartbeats should be performed although absence may not indicate fetal death. Fetal heart rates below 200 bpm may indicate fetal compromise and dictates need for immediate treatment. If obstruction of the birth canal is suspected, surgery rather than medical therapy should be chosen. Therefore, abdominal radiographs are recommended to evaluate fetal size and position related to the birth canal of the dam. Abdominal ultrasound should be performed to determine fetal viability and presence of uterine or abdominal fluid that may indicate infection or peritonitis, respectively.

In a periparturient bitch that demonstrates signs of compromise, a CBC and serum chemistry should be performed to aid in evaluating for sepsis, hypoglycemia, hypocalcemia, and her general health. Parenteral oxytocin administration, with or wit hout calcium and glucose, may be all that is needed. Often, however, dogs and cats with dystocia usually require C-section. It is important to consider the effects of anesthesia on the bitch and fetus. Anesthetic protocols should be chosen to minimize respiratory depression of either fetus or the bitch. Surgical preparation of the bitch needs to be performed prior to anesthesia induction, which decreases exposure of bitch and fetus to cardiac and respiratory depression caused by general anesthetics. The physiologic changes of the pregnant bitch should also be taken into consideration and appropriate measures taken to treat respiratory and cardiovascular compromise due to increases in intra-abdominal pressure. Supplemental oxygen during anesthesia induction, along with intravenous fluid administration and tilting the surgery table toward the surgeon during surgery, are recommended.

450
451

Fluid therapy may be needed to correct dehydration due to vomiting or hypovolemia due to shock. Pregnant bitches may be prone to vomiting. Therefore antiemetics may be needed. Care should be taken to resuscitate neonates. Therefore trained staff should be available to remove fetal membranes, stimulate respiration, remove fluid from their nares using gentle suction, and to ensure proper clamping and cutting of umbilical cords. Proper care of neonates has been reviewed elsewhere.

122.2 ECLAMPSIA

Hypocalcemia usually occurs in the second or third weeks of lactation. Less commonly, hypocalcemia occurs in the first or fourth weeks of lactation. Rarely, it is diagnosed in the final 1 or 2 weeks of gestation. Hypocalcemia is due to a loss of calcium into the milk more rapidly than it can be absorbed from bone and because some of these dogs fail to eat properly. Predisposing factors are high-calcium diet during pregnancy, calcium supplementation during pregnancy, and heavy lactation demands postpartum. Clinical signs include nervousness, panting, salivation, stiff gait, ataxia, and clonic-tonic muscle contractions that may progress to seizures. If not treated, death may result. Diagnosis is usually based on history and clinical signs. Laboratory finding of hypocalcemia is not usually necessary. If assessed, total serum calcium concentrations are usually below 7 mg/dL in bitches and less than 8 mg/dL in queens. Serum ionized calcium concentrations provide more direct information on biologically available calcium. However, treatment should be instituted before serum calcium results are available, if blood is taken.

Calcium should be administered intravenously slowly at 5 to 10 mL increments. The heart should be monitored for bradycardia and arrhythmias during calcium administration via auscultation and ECG. A 10% to 20% calcium gluconate solution is usually given; however, other calcium preparations have been used. Once acute signs have resolved, subcutaneous calcium may be given at 8-hour intervals. Caution is advised in the choice of calcium supplements since calcium concentration differs and some are irritating when given IM or SQ. Dogs and cats should then be placed on oral calcium supplementation for the remainder of their lactation period with close monitoring for return of clinical signs. If signs return, puppies or kittens should be weaned or bottle-fed.

122.3 METRITIS

Metritis may occur during the postpartum period due to obstetric manipulations, retained fetal remains, or retained placenta. Clinical signs may include reddish brown fetid vaginal discharge, fever, anorexia, lethargy, or lack of interest in the neonate. Physical examination may reveal an enlarged uterus and clinical signs of sepsis. Abdominal radiographs and ultrasound should confirm the presence of an enlarged, fluid-filled uterus. The CBC typically reveals a leukocytosis, neutrophilia, and a left shift. Serum chemistry profiles reflect degree of dehydration and may demonstrate hypoglycemia in some septic animals. Increases in liver enzyme activities may occur due to endotoxemia. Abdominal ultrasound may be used to determine the thickness of the uterine wall. If there is evidence of a thin uterine wall or medical therapy is unsuccessful, ovariohysterectomy is recommended. Medical therapy consists of oxytocin or prostaglandin therapy for emptying the uterus. Broad-spectrum antibiotics should be administered also chosen with consideration of the nursing neonate.

122.4 MASTITIS

Mastitis is bacterial infection of the mammary gland. Clinical signs can occur during the postpartum period alone or accompanying metritis or in pseudopregnancy. Clinical signs may include fever, anorexia, lethargy, and lack of interest in the neonate. Physical examination may reveal fever, hardened, painful mammary glands, and in some cases gangrenous mammary glands. Infection of the mammary gland is considered ascending but could be due to hematogenous spread. Diagnosis is based on history, clinical signs, and physical examination findings. Cytology and culture of mastitic milk often reveals degenerating neutrophils and, typically, pure colonies of staphylococci, streptococci, or *Escherichia coli*. Treatment consists of broad-spectrum antibiotics while culture results are obtained. The dog or cat should be switched to an appropriate antibiotic after culture results are obtained. Choice of antibiotic should consider the nursing neonate. Puppies or kittens should be allowed to nurse (actually encouraged) except if the glands are abscessed or gangrenous. Abscessed and/or gangrenous glands should be surgically treated.

122.5 UTERINE TORSION

Uterine torsion refers to rotation of one or both uterine horns. The condition is uncommon and can occur in the gravid or non-gravid uterus. Uterine torsion occurs more often during pregnancy and is more common in the queen than the bitch. Clinical signs are abdominal pain and shock. Acute abdominal enlargement may be seen in the non-pregnant female and signs of dystocia in the pregnant female. A high degree of suspicion of uterine torsion is made in the bitch or queen experiencing abdominal pain, enlarged uterus, and radiographic signs of uterine gas or acute distention of the abdomen. Definitive diagnosis is made by exploratory laparotomy. An immediate ovariohysterectomy is required. Appropriate fluid therapy should be administered to combat shock and broad-spectrum antibiotic should be administered for infection. Saving the life of the queen or bitch is more important than preservation of their reproductive potential.

122.6 PYOMETRA

Pyometra and cystic endometrial hyperplasia are common illnesses in older nulliparous bitches and queens. During diestrus, the endometrial glands of the uterus are stimulated, which causes hyperplasia and hypersecretion leading to cystic endometrial hyperplasia. Pyometra is uterine inflammation and bacterial infection that leads to an accumulation of pus in the uterine lumen. Most bitches with pyometra are seen during diestrus, whereas queens

are brought to veterinarians post estrus. The pathophysiology is not completely understood but is considered due to multiple exposure of the uterus to progesterone. Pathophysiology has been reviewed elsewhere.

The disease has been further divided into open and closed cervix distinctions based on the degree of cervical patency. Usually the bitch has a history of predisposing factors such as multiple estrous cycles, use of exogenous estrogen, or use of progestins. Clinical signs, often more severe in animals with closed cervix pyometra, include anorexia, fever, vomiting, polyuria, and polydipsia. Animals with "open-cervix" pyometra have a purulent vaginal discharge. Sepsis, endotoxemia, and renal failure can occur in some bitches with pyometra. Vaginal discharge with systemic signs and history of estrus 1 to 12 weeks prior to development of clinical signs leads to the suspicions of pyometra. Blood work abnormalities consist of a neutrophilia with a left shift and non-regenerative anemia. Azotemia, the raised serum protein concentrations (both albumin and globulin) and elevated liver enzymes are seen. These changes are caused by dehydration and endotoxemia. Urinalysis reveals normal to low urine specific gravity and sometimes proteinuria. Urinary tract infection occurs in some cases. The most common bacteria associated with pyometra are *E. coli,* although streptococci, staphylococci, and *Proteus* and *Klebsiella* spp. have also been reported. Diagnosis, based on history and clinical signs, is usually confirmed by radiography and/or ultrasound. Lateral radiographic views of the abdomen are most helpful. An enlarged sacculated uterus can be seen, especially in animals with closed-cervix pyometra. This cannot be distinguished from a pregnant uterus less than 42 days into gestation. Abdominal ultrasound is valuable for the diagnosis of pyometra. A fluid filled uterus can be visualized and differentiated from fetal sacs. Medical and surgical treatment options exist but surgery is usually recommended. Dehydration and sepsis is addressed first with fluid therapy and broad-spectrum antibiotics. Medical treatment with prostaglandin can be used if the cervix is open. Treatment protocols with natural prostaglandin have been reviewed elsewhere. Surgical treatment consists of ovariohysterectomy. Stabilization of the dog or cat with fluids and antibiotics is required before any treatment medical or surgical. Antibiotic therapy should be continued for 1 month.

In summary gynecologic emergencies may be challenging. Knowledge of clinical signs and reproductive history is critical to diagnosis. A complete physical examination and laboratory workup is necessary to determine complications associated with each emergency.

123 CHAPTER • 123 Sepsis and the Systemic Inflammatory Response Syndrome

Linda Barton

Stedman's Medical Dictionary defines sepsis as “the presence of various pus-forming and other pathogenic organisms, or their toxins, in the blood or tissues.” However, increased understanding of the pathogenesis of sepsis has shifted the focus from the microorganisms causing infection to the host's response to that infection. The clinical syndrome of sepsis represents the body's systemic response to infection, characterized by signs of inflammation, particularly when that response becomes deleterious to the host.

The human and veterinary medical literature has used a variety of terms interchangeably to describe patients with adverse systemic manifestations of infection. In an attempt to standardize the literature and to identify homogeneous patient populations for clinical trials, a consensus conference was sponsored in 1991 by the American College of Chest Physicians and the Society of Critical Care Medicine. The consensus conference agreed on definitions for the terms *bacteremia, sepsis, severe sepsis, septic shock,* and *multiple organ dysfunction syndrome* (MODS) (Box 123-1). Conference attendees recognized the clinical course of sepsis as a continuum. *Sepsis* is the term used to describe patients with infection-induced systemic inflammation. The occurrence of organ dysfunction secondary to sepsis is defined as *severe sepsis*. The development of hypotension, not responsive to IV fluid administration, is defined as *septic shock.*

Recognizing that severe insults other than infection can produce a generalized systemic reaction, organ dysfunction, and shock indistinguishable from those induced by sepsis, conference attendees created the term *systemic inflammatory response syndrome* (SIRS). SIRS can be used to describe evidence of systemic inflammation due to either an infectious or noninfectious process. Only when SIRS is associated with infection is it defined as sepsis. The SIRS criteria have been modified for the cat and dog (Table 123-1). Noninfectious processes associated with SIRS in animals include pancreatitis, tissue trauma, heat stroke, ischemia, burns, and pansystemic neoplasia.

123.1 PATHOGENESIS

Infection or tissue injury triggers a local immune response. Toxic effects from infecting organisms, components of infecting organisms (such as endotoxin, the lipopolysaccharide associated with the membrane of gram-negative bacteria), exotoxins, or aminophospholipids from damaged cell membranes stimulate the release of a variety of pro-inflammatory and anti-inflammatory mediators into the local environment. This local immune response is a desired host defense. In some individuals, inflammatory mediators spill over into the systemic circulation, which triggers a more generalized reaction. A systemic inflammatory reaction is more likely to develop with a severe insult or when a patient receives sequential insults. The “second-hit” theory proposes that patients with a controlled inflammatory process may develop SIRS if they sustain a second infectious or inflammatory insult.

The clinical manifestation of this generalized reaction depends on the balance between pro-inflammatory and anti-inflammatory mediators. In a controlled response, pro-inflammatory and anti-inflammatory cascades are balanced and homeostasis is restored. An imbalance in favor of anti-inflammatory cytokines results in relative immunosuppression. SIRS/sepsis and the progression to severe sepsis and septic shock result from an imbalance in favor of the pro-inflammatory mediators.

123.1.1 Box • 123-1 1991 ACCP/SCCM Consensus Conference Definitions

Bacteremia: The presence of viable bacteria in the blood.

Systemic Inflammatory Response Syndrome (SIRS): The systemic inflammatory response to a variety of infectious or non-infectious insults. The response is manifested by two or more of the following criteria:

Temperature >38°C or <36°C

Heart rate >90 beats/minute

Respiratory rate >20 breaths/minute or $PaCO_2$ <32 torr

WBC >12,000 cells/mm^3, <4000 cells/mm^3, or >10% immature (band) forms Sepsis: The systemic response to infection. SIRS as a result of infection.

Severe sepsis: Sepsis associated with organ dysfunction, hypoperfusion or hypotension. Clinical manifestations include lactic acidosis, oliguria and altered mentation.

Septic shock: Sepsis with hypotension, despite adequate fluid resuscitation.

Multiple Organ Dysfunction Syndrome (MODS): The presence of altered organ function in an acutely ill patient such that homeostasis cannot be maintained without intervention.

The clinical signs of SIRS, organ dysfunction, and septic shock are produced by the pathophysiologic effects of inflammatory mediators. The effects on the cardiovascular system are characterized by peripheral vasodilation, which results in decreased systemic vascular resistance and myocardial dysfunction manifest as ventricular dilation, a decreased ejection fraction, impaired contractile response to volume loading, and decreased left ventricular compliance. Vascular endothelial injury occurs secondary to enhanced neutrophil activation and adhesion, which leads to increased vascular permeability.

Interactions between inflammatory and coagulation cascades during sepsis have become increasingly apparent. Large quantities of tissue factor (TF), the important trigger of the extrinsic coagulation cascade, are expressed by injured endothelial cells, and cytokine-stimulated neutrophils and macrophages. The procoagulatory state created by increased TF is further amplified by consumption of naturally occurring anticoagulants such as activated protein C, tissue factor pathway inhibitor, and antithrombin. Enhanced thrombin formation leads to deposition of fibrin in the microvasculature, which obstructs blood flow and exacerbates tissue hypoxia. This condition may progress to fulminant disseminated intravascular coagulation (DIC).

Table • 123-1 Criteria for Systemic Inflammatory Response Syndrome

CLINICAL PARAMETERS	DOGS	CATS
Heart rate	>120 bpm	<140 bpm or >225 bpm
Respiratory rate	>40 bpm or $Paco_2$ <30 mm Hg	>40 bpm
Temperature	<100.4° F or >104.0° F	<100.0° F or >104.0° F
Leukogram	>18,000 or <5000 WBC/µL	>19,000 or <5000 WBC/µL

123.2 CLINICAL PRESENTATION AND DIAGNOSIS

Recognizing SIRS/sepsis and its sequelae as a continuum, clinical signs vary from animals with mild abnormalities to those with signs of organ dysfunction and septic shock. No single set of clinical, laboratory, and hemodynamic parameters can describe all situations. In addition to the SIRS-related changes in body temperature, heart rate, respiratory rate, and white blood cell count, affected animals may have decreased mentation, hypotension, bounding or hypodynamic peripheral pulses, thrombocytopenia, hypoalbuminemia, hypoglycemia, prolonged clotting times, increased fibrin split products, increased D-dimer, decreased antithrombin, increased bilirubin, increased liver enzymes, increased BUN/creatinine, oliguria, lactic acidosis, and/or hypoxemia.

The animal may have signs related to the underlying infection (i.e., coughing and dyspnea associated with bacterial pneumonia). Alternatively, the systemic inflammatory response may manifest before signs of the infection and should alert the clinician to search for an infectious cause. When animals have unexplained shock (no history or physical exam findings consistent with trauma, blood or fluid loss, or cardiac disease) sepsis should be suspected as the underlying cause.

Suspicion of sepsis demands an “infection hunt.” Common causes of sepsis in dogs and cats include peritonitis, pyometra, prostatitis, prostatic abscess, pyelonephritis, pneumonia, pyothorax, and endocarditis. In hospitalized animals, nosocomial infections should be considered. IV catheters, urinary catheters, and other invasive devices should be carefully inspected and removed, as required. Translocation of bacteria from a diseased or unused GI tract is another possible source of infection. Signalment, history, and physical exam are useful in localizing the nidus of infection. Samples should be collected for CBC, serum biochemical profile, and urinalysis to assist in the localization of infection and to detect evidence of organ dysfunction. Additional information may be provided by evaluation of an arterial blood gas or coagulation profile. Radiographs and ultrasound of the thorax and abdomen may also be indicated.

453 454

123.3 TREATMENT

Therapy of sepsis has three major components: first to identify and eradicate the infection, second is supportive care to maintain adequate tissue perfusion and minimize organ dysfunction, and finally therapy to alter the pathologic inflammatory cascade. The prognosis declines as SIRS/sepsis progresses to septic shock and MODS, which emphasizes the importance of early recognition and treatment.

Rapid institution of appropriate antibiotic therapy has been shown to improve survival in humans with sepsis. Empiric parenteral broad-spectrum antibiotic therapy should be initiated following collection of appropriate culture specimens (bronchoalveolar fluid, urine, blood, wound drainage, loculated fluid, or IV catheter tip) and can be modified when results of culture and sensitivity are available. In animals with an unknown infection source, blood and urine cultures should be obtained. The agent chosen depends on the host status and the suspected causative organism. Important factors to consider include the suspected source of infection, nature of the pathogen most likely responsible (community-acquired or nosocomial), local resistance patterns, and underlying immune status. Sepsis in dogs and cats is most often associated with gram-negative enteric bacteria. Prevalence of common bacterial isolates based on site of infection in dogs and cats has been reported. In addition to antibiotic therapy, surgical drainage of abscesses, and debridement of infected or devitalized tissue may be necessary to remove the nidus of infection/inflammation.

As the infection/inflammation resolves, animals must be aggressively monitored and supported to ensure adequate organ and tissue perfusion. Hypoperfusion can be detected by changes in physical exam parameters (decreased

mentation, tachycardia [or bradycardia in cats], prolonged CRT, decreased pulse quality, decreased extremity temperature), decreased arterial blood pressure, oliguria, or development of hyperlactemia. Most affected animals have decreased preload caused by fluid leakage secondary to increased vascular permeability. Vasodilation of peripheral vessels and maldistribution of blood flow cause a relative hypovolemia. Therefore volume resuscitation is the best initial therapy for hypoperfusion. Aggressive volume administration is best guided by measurement of central venous pressure (CVP) or ideally pulmonary capillary wedge pressure (PCWP). IV fluid boluses (15 to 20 mL/kg isotonic crystalloid, or 5 mL/kg colloid) should be administered until normal perfusion has been restored or until risk of volume overload and pulmonary edema are evident (CVP >8 cm H_2O or PCWP >18 mm Hg). Use of colloids is thought to prevent the development of interstitial edema in patients with increased vascular permeability, although there is no proven advantage of colloid over crystalloid fluid therapy. The type of fluid administered is probably less important than the rapidity with which resuscitation is achieved and the use of physiologic end points to evaluate the response to therapy.

If fluid therapy alone fails to restore adequate blood pressure and perfusion, vasopressor agents should be added. Dopamine (5 to 20 μg/kg/min) increases systemic blood pressure through both improved cardiac performance (β-agonist effect) and increased systemic vascular resistance (α-agonist effect). The vasopressor effect predominates at the higher end of the dose range. Therefore to prevent excessive vasoconstriction of peripheral and splanchnic vessels, dopamine should be started at 5 μg/kg/min and the dose titrated to effect. Evidence in human patients suggests that norepinephrine (0.25 to 2.0 μg/kg/min) is superior to dopamine in the treatment of hypotension associated with septic shock.

Oxygen delivery to tissues depends not only on the volume of blood delivered but also on the oxygen content of the arterial blood. To ensure normal oxygen delivery, factors that affect blood oxygen content should be monitored. Hemoglobin concentration should be maintained at at least 8 g/dL (PCV ≥24%) and hemoglobin saturation at at least 90%. Transfusions of pRBCs, Oxyglobin, supplemental oxygen, and/or mechanical ventilation should be used as needed to optimize oxygen delivery to the tissues.

Serial monitoring of key organ systems (the cardiovascular, pulmonary, coagulation renal gastrointestinal and central nervous systems are commonly affected in sepsis) is necessary to detect early derangements in function. Electrolytes and blood glucose should be monitored and supplemented as needed. Enteral nutrition is important to support host defenses and bowel integrity.

The final goal of therapy is to control or inhibit the actions of the inflammatory cascade. Clinical trials of a number of specific anti-inflammatory therapies, including antibody to endotoxin, IL-1 receptor antibody, antibradykinin, antiplatelet activacting factor, anti-TNF, and high-dose glucocorticoids, have been conducted in humans, and with the exception of activated protein C (APC) have not demonstrated a significant reduction in mortality. Drotrecogin alfa (activated), a human recombinant APC with antithrombotic, profibrinolytic, and anti-inflammatory properties, demonstrated a significant reduction in mortality in humans with severe sepsis and received FDA approval in 2001. The cost of the drug (approximately $6,800/person) will prohibit its use in veterinary medicine.

Until cost-effective specific anti-inflammatory therapies become available, optimal management of the septic veterinary patient will depend on rapid recognition, eradication of the source of infection/inflammation, and meticulous supportive care directed at restoring normal oxygen delivery to tissues.

124 CHAPTER • 124 Shock

Cynthia M. Otto

Shock is not a disease but a complex physiologic state. Historically, shock was described as the effect of generalized circulatory abnormalities that led to inadequate tissue perfusion. Although this classic description still holds important clinical relevance, the complexity of shock states result not from the initial insult per se, but the systemic response to that insult. This is most clearly demonstrated in septic shock, in which the cascade of events that leads to irreversible cardiovascular collapse is the systemic inflammatory response initiated by products of infectious agents. This systemic inflammatory response syndrome (SIRS) can also be triggered by noninfectious insults including tissue hypoxia, tissue acidosis, pancreatitis, trauma, and major surgery. Similarly, although hypovolemia can be reversed, reperfusion of ischemic tissues leads to inflammation, and production and release of mediators. These complex cascades confound the treatment of shock; reversing the perfusion abnormalities may not stop the progression once the inflammatory cascade has been initiated. Treatment directed at the downstream cellular mediators of shock has not proven beneficial either. Whether the cause is infection, blood loss, or tissue hypoxia, one of the most successful approaches to the treatment of shock is early recognition and correction of the inciting cause before the cascade of inflammation is triggered.

Shock is a dynamic state and the clinical condition can change in a matter of minutes, hours, or even days. Early stages of shock may not be clinically obvious, as the compensatory mechanisms are recruited to maintain cardiac output and tissue perfusion. In late stages of shock, compensatory mechanisms fail; systemic inflammation leads to multiple organ dysfunction and death. In these late stages of shock, successful clinical intervention is uncommon. This chapter focuses on the clinical presentations associated with the three major types of shock in the early and intermediate stages of shock. Shock is classically divided into three main categories based on the mechanisms of impaired perfusion: cardiogenic, hypovolemic, and distributive.

124.1 TYPES OF SHOCK

Cardiogenic shock results predominantly from failure of adequate forward flow. The dysfunction can occur in either the diastolic or systolic phase or can result from an obstruction of flow. Systolic or forward flow failure results from overt heart failure or severe tachyarrhythmias. Diastolic or filling failure can result from pericardial tamponade, tension pneumothorax, or hypertrophic cardiomyopathy. Obstructive shock can be the result of thromboembolic disease, tumors, or distended organs (e.g., gastric dilatation and volvulus; GDV) occluding either forward flow or venous return. The location, degree of obstruction, and resulting compromise to systemic perfusion are important determinants of whether flow occlusion will lead to shock.

Hypovolemic shock leads to inadequate delivery of oxygen and nutrients to tissues and accumulation of byproducts of cellular metabolism due to insufficient circulating blood volume. Intravascular volume depletion can result from acute or chronic fluid loss or sequestration of fluids into third spaces.

Distributive shock is a condition in which the effective circulating volume is inadequate to provide tissue perfusion. The classic example of distributive shock is septic shock. However, other vasodilatory states can also lead to distributive shock such as heat stroke, anaphylaxis, neurogenic shock, and SIRS. The common defect in distributive shock is inappropriate vasodilation, which leads to a relative hypovolemia. Sepsis and heat stroke are both complicated by a vigorous systemic inflammatory response and further compromised tissue oxygenation due to maldistribution of blood flow and mitochondrial dysfunction.

The types of shock vary in their etiology, clinical signs, and treatment. The categories of shock are not mutually exclusive and many animals with distributive shock will also have some degree of hypovolemia, particularly as SIRS leads to increased vascular permeability and fluid loss. Mediators of SIRS and ischemia reperfusion injury include substances that contribute to cardiac dysfunction. Thus progression of both distributive and hypovolemic shock can lead to cardiogenic shock. Cardiac patients are frequently volume-depleted. Any animal with inadequate intestinal perfusion may develop bacterial translocation and sepsis. Unrecognized, untreated shock initiates a cascade of doom. Therefore early recognition based on index of suspicion, aggressive monitoring in patients at risk, and appropriate interventions are essential in the successful treatment of shock states.

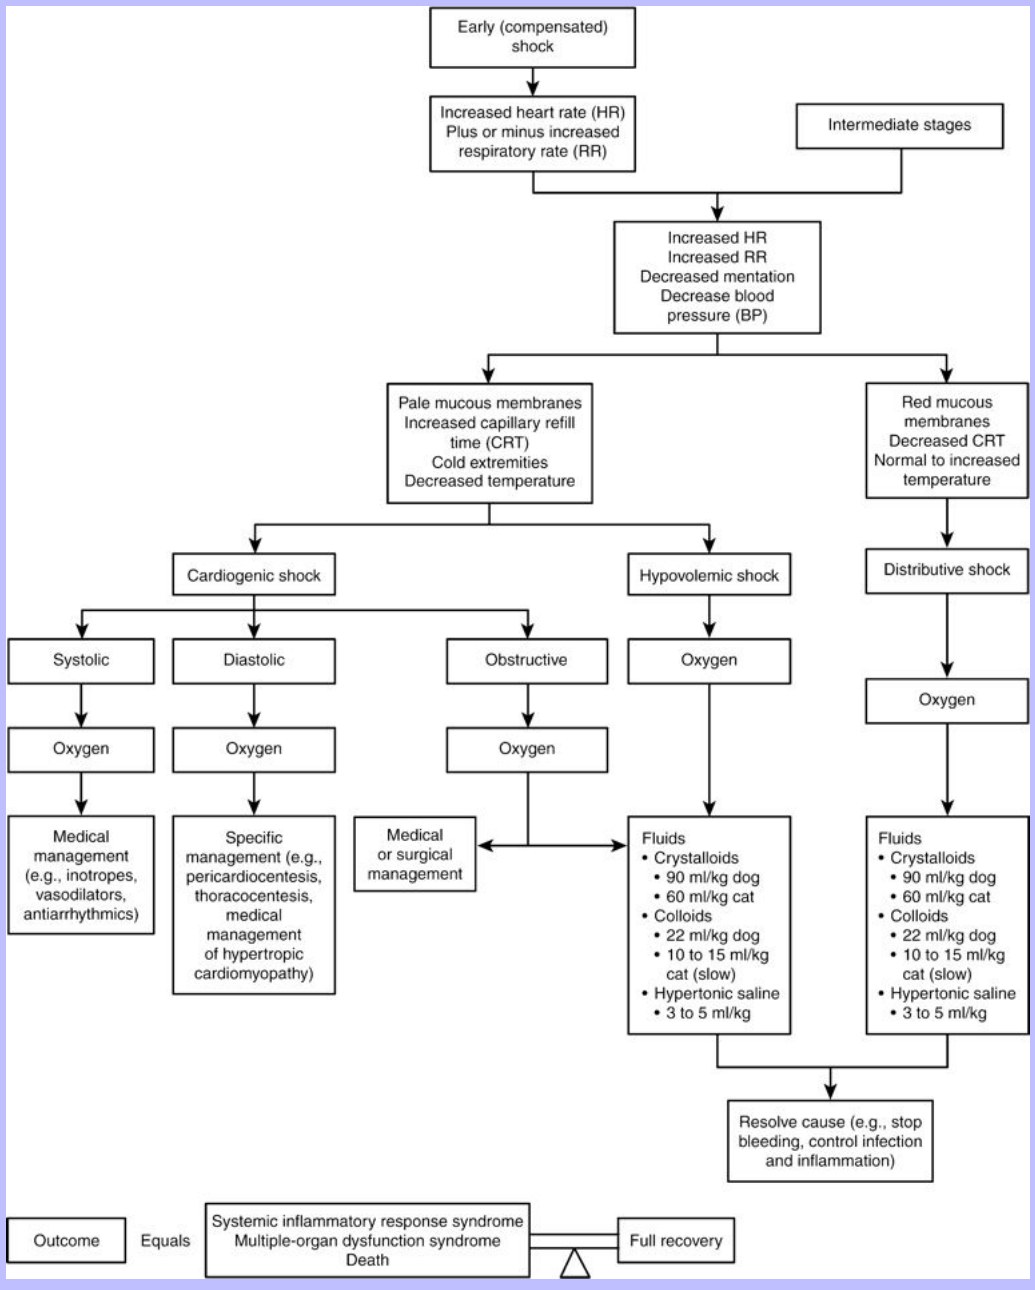
124.2 CLINICAL SIGNS OF SHOCK

The normal physiologic response to poor tissue perfusion is to increase sympathetic tone, which results in increased heart rate, respiratory rate, and vasoconstriction. In the early (sometimes called *compensated*) stages, tachycardia may be the only clinical sign. With time and progression to the intermediate stages (also referred to as *early decompensated*), profound vasoconstriction results from the attempt to increase venous return and maintain stroke volume. In the intermediate stages, additional compensatory mechanisms trigger an increase in salt and water retention (angiotensin-aldosterone and ADH) and release of vasoconstrictors (e.g., vasopressin), that contribute to an increase in stroke volume. Clinically these compensatory mechanisms result in signs typically seen in cardiogenic and hypovolemic shock, including pale to white mucous membranes, a prolonged capillary refill time (>2 sec), cool extremities, a normal to decreased rectal temperature, decreased mentation, tachypnea, and hypotension. Although the overall compensatory response is consistent regardless of the etiology, the hallmark of distributive shock is the failure of effective vasoconstriction. The circulating mediators released in response to sepsis or SIRS result in vasodilation that leads to an effective hypovolemia. The clinical signs associated with distributive shock include red mucous membranes, rapid capillary refill time (<1 sec), and normal or increased rectal temperature. Distributive shock also leads to dysregulation of the normal stress response, and although hyperglycemia may be seen early, classically it is hypoglycemia that is associated with distributive (septic) shock. One other unique feature of distributive shock is that cats frequently become bradycardic rather than tachycardic.

455

457

Figure 124-1 Algorithm for assessment and treatment of shock. *HR*, Heart rate; *RR,* respiratory rate; *mm,* mucous membranes; *CRT,* capillary refill time; *T*, rectal temperature; *BP*, blood pressure; *mgt,* management; *HCM,* hypertrophic cardiomyopathy; *SIRS,* systemic inflammatory response syndrome; *MODS,* multiple organ dysfunction syndrome.



In order to differentiate cardiogenic shock from hypovolemic shock, a thorough cardiac evaluation and complete history are beneficial. Unfortunately, animals in shock are frequently not stable enough to obtain extensive diagnostic tests and therapy needs to be initiated based on physical examination and historical findings. Distributive shock that is complicated by concurrent fluid loss (due to changes in vascular permeability and fluid compartment shifts or the underlying etiology) may initially demonstrate clinical signs more typical of hypovolemic shock, but upon resuscitation, develop clinical signs of distributive shock.

124.3 TREATMENT OF SHOCK

The goal of treatment in early shock is to restore effective tissue perfusion and oxygenation (Figure 124-1). In later stages of shock, restoration of perfusion alone is usually insufficient to halt the progression of the inflammatory cascade. Aggressive support of organ function and prevention of additional pro-inflammatory complications (including hypotension, hypoxia, and infection) are critical. At all stages, correction of the inciting cause is necessary.

Oxygen is universally administered in patients regardless of the type of shock. Additional therapy depends on the etiology of the shock. For both hypovolemic and distributive shock, fluid therapy is essential (see Chapter 114). The goal is to increase the effective circulating volume. The choice of fluids depends on the cause of shock; however, initial treatment is typically provided by crystalloids (balanced electrolyte solutions) at volumes of approximately 90 mL/kg in the dog and 60 mL/kg in the cat. The fluid rate and the actual volume given should be tailored to each individual animal. Typically, one fourth of the bolus is provided within the first 5 to 15 minutes, with repeated evaluation of the cardiovascular response (e.g., heart rate, mucous membrane color, pulse quality, and capillary refill time). Colloids can be used for shock resuscitation (22 mL/kg bolus in dogs, and 10 to 15 mL/kg infusion in cats) of hypoproteinemic animals and in conjunction with (reducing the volumes of both fluid types) or instead of crystalloids. Due to potential anticoagulant effects, colloid administration generally should not exceed 22 mL/kg per day. (For a more extensive discussion of fluid therapy see Chapter 114). The resuscitative fluid of choice for hemorrhagic hypovolemic shock is blood. Typical recommendations limit blood transfusions to 22 mL/kg; however, massive transfusions (greater than one blood volume) may be required in some cases (see Chapter 127). Hypertonic saline (HTS) is typically mixed with a colloid (to a final concentration of 7% saline) and may be considered for resuscitation at 3 to 5 mL/kg over 5 to 20 minutes. The small volumes required may be particularly beneficial in larger animals in which volumes of crystalloid are rate limiting. The hypertonic nature may also be beneficial in animals with shock and concurrent head injury. It has been demonstrated, however, that HTS, and other therapies that rapidly increase blood pressure may predispose to excessive bleeding in uncontrolled hemorrhage.

In cardiogenic shock, aggressive fluid therapy may be fatal. Treatment of cardiogenic shock relies on correction of the underlying cause. For systolic dysfunction, treatment of arrhythmias, diuretics, vasodilators, or inotropes may be required (see Chapter 199). Pericardiocentesis is necessary for treatment of tamponade and thoracocentesis/chest tube placement for tension pneumothorax. Diastolic dysfunction resulting from cardiac hypertrophy can be a challenge to treat (see Chapter 204). Resolution of obstruction to flow may require surgical intervention (e.g., tumors, GDV) or medical management (e.g., thromboembolic disease). Prior to surgery, adequate circulatory volume and optimal perfusion should be established.

Specific therapy should be directed at the cause of shock, such as in hemorrhagic hypovolemia, bleeding must be controlled and in septic shock the source of infection must be eliminated. Vasopressors may be required in distributive shock when hypotension persists despite adequate volume repletion. Detailed discussion of sepsis can be found in Chapters 123 and 124. Despite over 30 years of investigation, specific anti-inflammatory therapies have generally failed in clinical trials of shock and sepsis (see sepsis chapter). Although long touted for beneficial

effects in shock, there is no clinical evidence to support pharmacologic doses of glucocorticoids in the treatment of any form of shock.

Monitoring is critical during the resuscitation of shock. In addition to routine cardiovascular parameters (e.g., heart rate, mucous membrane color, pulse quality, and capillary refill time), respiratory rate, temperature, mentation, blood pressure monitoring (see Chapter 124), hematocrit, electrolytes, blood gases, base excess and lactate may help direct therapy. Central venous pressure monitoring is invaluable in shock to aid in determination of volume status and guide fluid resuscitation. More advanced monitoring that may be beneficial in managing the shock patient include cardiac output, oxygen delivery, oxygen extraction, and pulmonary capillary wedge pressure.

125 CHAPTER • 125 Systemic Anaphylaxis

Lori S. Waddell

Systemic anaphylaxis is an acute, life-threatening allergic reaction resulting from massive, generalized release of mast cell mediators, including histamine. Anaphylaxis can be triggered by venoms from insects and reptiles; medications, including hormones, antibiotics, nonsteroidal anti-inflammatory drugs, anesthetics, and sedatives; parasiticides; and other miscellaneous drugs and foods (Box 125-1). Immediate recognition and treatment of the veterinary patient with anaphylaxis is essential for a successful outcome.

125.1 Box • 125-1 Causes of Anaphylaxis

125.1.1 Venoms

Insects of the Hymenoptera order—bees, wasps, ants

Spiders—black widow, brown recluse

Lizards—Gila monster, Mexican beaded lizard

Snakes—pit vipers (rattlesnakes, copperheads, water moccasins), coral snakes

125.1.2 Hormones

Insulin

Corticotropin

Vasopressin

Parathyroid hormone

Betamethasone

Triamcinolone

125.1.3 Antibiotics

Penicillins—amoxicillin, ampicillin, procaine penicillin

Chloramphenicol

Lincomycin

Gentamicin

Tetracycline

Sulfonamides

Cephalosporins

Polymixin B

Doxorubicin hydrochloride

125.1.4 Nonsteroidal Anti-Inflammatory Drugs

Aspirin

Ibuprofen

125.1.5 Anesthetics and Sedatives

Acepromazine maleate

Ketamine hydrochloride

Barbituates

Lidocaine and other local anesthetics

Narcotics

Diazepam

125.1.6 Parasiticides

Dicholophen

Levamisole hydrochloride

Piperazine

Dichlorvos

Diethylcarbamazine

Thiacetarsamide

125.1.7 Miscellaneous

Blood products

Aminophylline

Asparaginase

Calcium disodium edetate

Iodinated contrast media

Neostigmine

Amphotericin B

Vaccines

Allergen extracts—pollens, molds, foods

Enzymes—chymotrypsin and trypsin

Vitamins—vitamin K, thiamine, and folic acid

Dextrans and gelatins

Milk

Egg

white

Shellfish

Legumes

Fruits—citrus

Chocolate

Grains

125.1.9 Physical Factors

Cold

Heat

Exercise

125.2 PATHOGENESIS

Anaphylaxis can be caused by either an anaphylactic or anaphylactoid reaction. Anaphylactic reactions are mediated by an interaction of antigen and IgE antibody on the surface of sensitized mast cells, which causes the release of histamine and other inflammatory mediators. This is defined as a type I, IgE mediated, hypersensitivity reaction. Sensitization requires previous exposure to an antigen or hapten, which can range in size from a protein to a small, low molecular weight drug. Proteins act directly as an antigen, while the smaller drugs will bind to cells and act as haptens. IgE is produced by and bound on the surface of mast cells and basophils by high-affinity receptors (FcεRI) for the Fc portion of the immunoglobulin. When an antigen causes cross-linkage of two surface IgE molecules, the mast cell is activated and primary and secondary mediators are released (Box 125-2). The

cross-linking of the FcεRI receptors activates tyrosine kinases, which cause activation of phospholipase C, leading to production of diacylglycerol and inositiol triphosphate. These mediators increase intracellular calcium concentrations and activate multiple protein kinases. Phosphorylation of myosin, found in intracellular filaments, causes granules to move to the cell surface, fuse, and release the primary mediators of anaphylaxis: histamine, heparin, tryptase, kallikreins, proteases, proteoglycans, eosinophilic chemotactic factor of anaphylaxis (ECF-A), and neutrophil chemotactic factor of anaphylaxis (NCF-A). Cross-linking of the FcεRI receptors also activates phospholipase A_2, which produces arachadonic acid from membrane phospolipids, which results in release of the secondary mediators: leukotrienes, prostaglandins, thromboxanes, and platelet-activating factor. The protein kinases also change gene expression, which results in synthesis and secretion of other cytokines (IL-4, IL-5, IL-6, IL-13, TNF-α, MIP-1α), which are responsible for the late-phase inflammatory response. Release of the inflammatory mediators is rapid: granule exocytosis occurs within seconds to minutes, activation of the arachadonic acid cascade in minutes, and cytokine synthesis and secretion within 2 to 24 hours.

Anaphylactoid reactions cause anaphylaxis without IgE, either through directly activating mast cells to release histamine, or more commonly, by activating the complement pathway. They do not require previous exposure and sensitization. Activation of complement results in production of C3a and C5a, the anaphylotoxins, which cause degranulation of mast cells and release of histamine and other primary mediators, activation of the arachidonic acid cascade, and gene expression and synthesis of the inflammatory mediators. Anaphylactoid and anaphylactic reactions have exactly the same clinical appearance and are treated identically.

125.2.1 Box • 125-2 Mediators of Inflammation in Anaphylaxis

Mediators	*Effects*
Primary	
Histamine	Increased vascular permeability, vasodilation, constriction of smooth muscle of bronchi and GI tract, increased mucus production
Proteases	Kinin production, activation of complement, initiation of disseminated intravascular coagulation
Heparin	Anticoagulation, urticaria, immune modulation
ECF-A	Eosinophil chemotaxis
NCF-A	Neutrophil chemotaxis
Secondary	
Prostaglandin E_2	Vasodilation, increased vascular permeability
Prostaglandin D_2	Bronchoconstriction, increased vascular permeability, pulmonary vasconstriction, peripheral vasodilation
Prostacyclin	Vasodilation, inhibition of platelet aggregation
Leukotrienes	Bronchoconstriction, increased vascular permeability, vasodilation, increased WBC chemotaxis
Thromboxane A_2	Increased platelet aggregation, smooth muscle contraction
Platelet activating factor	Platelet aggregation, platelet sequestration, increased platelet thromboxane production, increased vascular permeability, vasoconstriction, and bronchoconstriction

125.3 CLINICAL MANIFESTATIONS

Anaphylaxis can result in hypotension, bronchospasm, urticaria, erythema, pruritis, pharyngeal and laryngeal edema, arrhythmias, vomiting, and hyperperistalsis. Clinical signs are dependent on species and method of exposure. In dogs, the liver is considered the shock organ, and clinical signs result from hepatic vein congestion and portal hypertension. Initial signs may include excitement, vomiting, defecation (often diarrhea), then progress to respiratory distress, collapse secondary to hypovolemic shock, and death within one hour if not treated. A dog

with anaphylaxis may have generalized wheals, angioedema (particularly of the face), pruritis, pale mucous membranes, poor capillary refill time, tachycardia, poor pulse quality, and appear depressed or even collapsed. Severe cases may result in respiratory distress secondary to upper airway obstruction from laryngeal and pharyngeal edema.

In cats, the lungs are considered the shock organ, and respiratory distress is the first sign in cats with systemic anaphylaxis. Respiratory distress results from airway obstruction secondary to laryngeal edema, bronchoconstriction, and increased mucus production. Other signs in cats include severe pruritis, vomiting, diarrhea, depression, and death. A cat with anaphylaxis usually has severe respiratory distress, some wheezes on auscultation, pale mucous membranes, poor capillary refill time, and poor pulse quality.

The most severe anaphylactic reactions are generally seen if the antigen is given by parental injection. Oral ingestion often causes vomiting, diarrhea, urticaria, and angioedema. Inhalation can result in rhinitis and bronchospasm. Topical administrations can cause conjunctivitis and urticaria with or without systemic signs. *459*

460

125.4 DIAGNOSIS

Diagnosis of systemic anaphylaxis is based on the history of exposure and peracute onset of clinical signs. Clinical signs often occur within seconds to minutes of exposure. Oral exposure can cause a delay of up to 30 minutes or longer before clinical signs appear.

125.5 TREATMENT

Initial treatment of a dog or cat presenting with anaphylaxis consists of the basics of emergency medicine. These include ensuring that the patient has a patent airway, is effectively breathing/ventilating, addressing cardiovascular dysfunction, and drugs and fluids as indicated. Dogs or cats having an anaphylactic reaction may have respiratory distress resulting from upper airway obstruction. The clinician should be prepared to intubate with an endotracheal tube or perform a tracheostomy if intubation is not possible. If respiratory distress without airway obstruction is present, oxygen should be administered by mask or flow-by during initial assessment and stabilization, and then by nasal catheter or oxygen cage. Vascular access is essential for treatment of these patients, both for fluid therapy and medications. Hypovolemic shock is a significant contributor to morbidity and mortality in anaphylaxis. Hypovolemia occurs secondary to increased vascular permeability and venous pooling. Fluid therapy, often starting with a shock bolus of crystalloids at a rate of 90 mL/kg/hr in dogs and 60 mL/kg/hr in cats, is indicated. Ongoing crystalloid therapy will be necessary at rates higher than maintenance to keep up with ongoing losses and will need to be tailored to the individual patient. Additional fluid therapy may include synthetic colloids, such as dextran or hetatstarch, given in small incremental boluses of 10 mL/kg/hr in dogs and 6 mL/kg/hr in cats. A constant rate infusion of synthetic colloids of 1 mL/kg/hr may also be used once the patient has been resuscitated. If a coagulopathy is present, blood products, especially fresh frozen plasma, may be necessary. This should be given at a dose of 10 to 20 mL/kg over several hours (or faster if needed for volume resuscitation). Fluid therapy is guided by clinical parameters inlcuding heart rate, pulse quality, mucous membrane color, capillary refill time, respiratory rate and effort, and packed cell volume and total solids.

Epinephrine is essential therapy for treatment of systemic anaphylaxis and should be administered immediately. A dose of 0.01mg/kg of the 1:10,000 solution given slowly IV is most effective, although 0.02 mg/kg can be given into the trachea if the patient is intubated and IV access cannot be obtained. Epinephrine can also be administered SQ or IM at a dose of 0.01 mg/kg in less severe cases. Epinephrine is useful because of its inotropic and chronotropic effects on the heart, bronchodilation, and increased intracellular concentrations of cyclic adenosine monophasphate, which decreases synthesis and release of inflammatory mediators of anaphylaxis. Heart rate,

rhythm, and blood pressure should be monitored when giving epinephrine, especially when given intravenously because of its ability to cause arrhythmias and hypertension (at high doses). Epinephrine and fluid therapy should begin to improve clinical signs within minutes. Dogs and cats ideally will be fully stabilized within an hour.

Other medications that may be useful in the treatment of systemic anaphylaxis include pressors, glucocorticoids, antihistamines, aminophylline, and atropine. Dopamine at a dose of 4 to 10 mcg/kg/min or other pressors may be used if refractory hypotension is present. Aminophylline may be used if bronchoconstriction is refractory to epinephrine. It will cause bronchodilation, increase respiratory drive, and increase contractility of the muscles of respiration. A dose of 10 mg/kg IV for dogs and 5 mg/kg IV for cats is recommended. Atropine at a dose of 0.02 to 0.04 IV or IM should be used if bradycardia is present despite epinephrine administration. Glucocorticoids are useful in blocking the arachadonic acid cascade and reducing the severity of the late-phase anaphylactic reactions. Doses of 1 to 2 mg/kg IV for dexamethasone have been recommended. It is essential that glucocorticoids not be used in place of epinephrine in the emergency situation as they have little effect on the immediate stages of anaphylaxis. Antihistamines competitively bind at the histamine receptors and block its effects. Diphenhydramine, a H_1 blocker, should be administered at 0.5 to 1.0 mg/kg slow IV or IM to reduce pruritis and angioedema. The H_2 blockers, cimetidine, ranitidine, and famotidine, can be used to decrease gastric acid secretion stimulated by histamine. Dose varies with each of the H_2 blockers. Antihistamines are also not very useful in the acute, life-threatening stage of anaphylaxis, but may be helpful after the patient has been stabilized.

Intense monitoring of the patient for at least 12 to 24 hours after the anaphylactic episode is essential. This should include respiratory rate and effort, heart rate and rhythm, blood pressure, pulse oximetry and/or arterial blood gases, coagulation parameters, renal and hepatic function, and PCV, total solids, and glucose. Other supportive care, such as ventilatory support, should be provided as needed. Avoidance of the trigger for anaphylaxis is prudent in the future. Careful questioning of the owner about recent exposure to insects, reptiles, foods, topical therapies, and medications is essential. Prognosis for a patient presenting with systemic anaphylaxis is variable. The earlier the patient receives appropriate therapy, the better the prognosis. This is especially important since death can ensue in 1 hour or less from time of exposure.

126 CHAPTER • 126 Thoracic Trauma

Matthew W. Beal

Trauma to the thorax can be classified as blunt or penetrating. Blunt thoracic trauma commonly occurs after motor vehicle accidents, falls from a height, human-animal interactions, and dog bites. Dog bites are also a commonly recognized cause of penetrating thoracic trauma along with gunshot wounds and impalement injuries. Independent of the cause of the trauma, it is critical for veterinarians to recognize that trauma is most commonly a multisystemic problem (polytrauma). This necessitates attention to the entire animal. Similarly, injuries to the thorax are rarely isolated and more commonly are identified in combination (e.g., pneumothorax and pulmonary contusion). Keys to maximizing the likelihood of a positive outcome in dogs and cats with thoracic trauma include thorough physical examinations, anticipation of common injuries, understanding the pathophysiology of those injuries, and a proactive method to their identification and treatment.

126.1 TRAUMA-ASSOCIATED PLEURAL SPACE PATHOLOGY

Trauma associated pleural space pathology includes pneumothorax, hemothorax, and diaphragmatic hernia. As a group, these injuries are most likely to manifest with varying degrees of dyspnea accompanied by muffled lung and heart sounds on auscultation of the thorax. Differentiating these injuries will be largely based on a thorough physical examination and aided by thoracocentesis and diagnostic imaging techniques.

126.1.1 Pneumothorax

Pneumothorax is the accumulation of air in the pleural space between the parietal and visceral pleurae and is one of the two most commonly recognized results of traumatic injury to the thorax. Traumatic pneumothorax is classified as “closed” or “open.” Closed pneumothorax may result from rapid compression of the thorax (and lungs) against a closed glottis, which causes alveolar disruption, laceration of the lung by a broken rib, rupture of bullae or blebs, or from pneumomediastinum. Air enters the pleural space from an injury to the thoracic wall in cases of open pneumothorax. Tension pneumothorax occurs due to a one-way-valve effect, in which air enters the pleural space during inspiration and cannot be evacuated during expiration. The resultant increase in intrapleural pressure results in hypoventilation and decreased venous return, manifesting with signs of severe respiratory and cardiovascular compromise.

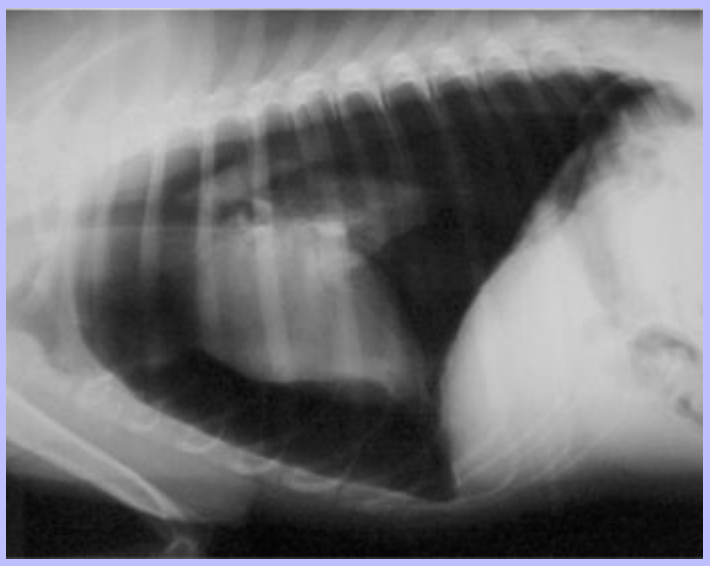
Appropriate management of the traumatized small animal patient necessitates the assumption that *pneumothorax is present until proven otherwise*. That assumption will remind the veterinarian to pay particular attention to those physical examination findings that will identify the problem. *Clinically significant pneumothorax is a physical examination diagnosis*. Most animals with pneumothorax prefer to stand or to position themselves in sternal recumbency. In this position, on auscultation, decreased lung sounds are most likely to be noted dorsally and most often are noted in both hemithoraces. Temporary relief and definitive diagnosis of pneumothorax is based on oxygen administration and bilateral thoracocentesis (see Chapter 103). Radiography for the diagnosis of clinically significant pneumothorax may jeopardize the stability of a dog or cat and should be avoided. When pneumothorax is noted on radiographs of a dog or cat that is not in distress after trauma, findings will include retraction of the lung from the chest wall (loss of vascular markings in this space), consolidation of lung lobes, and on lateral radiographs, the appearance of the heart “floating” on a cushion of air (Figure 126-1). The latter radiographic finding is due to collapse of the heart to the side of the atelectatic lung lobe. Often, a single thoracocentesis is sufficient treatment for traumatic closed pneumothorax. However, if pneumothorax recurs (sometimes rapidly), thoracostomy tube placement and continuous pleural

space drainage are recommended. Closed traumatic pneumothorax is rarely a condition that requires surgical correction. Open pneumothorax warrants immediate covering of the wound with an occlusive dressing and evacuation of the thorax by thoracocentesis or thoracostomy tube placement. Once stability has been achieved, open pneumothorax is *always* managed surgically (see Penetrating Thoracic Injury).

126.1.2 Hemothorax

Hemothorax is the accumulation of blood in the pleural space. Hemothorax results from disruption of pulmonary, thoracic wall, or mediastinal blood vessels. Hemothorax can also be seen in dogs and cats with diaphragmatic hernia and concurrent hemoabdomen. *Clinically significant hemothorax (although uncommon) is a physical examination diagnosis*. Hemothorax results in decreased lung and heart sounds ventrally to diffusely 461
and concurrent signs of hypovolemic shock (pale mucous membranes, slow CRT, high heart rate, weak pulses) 462
and dyspnea. The volume of blood loss necessary to cause signs of hypovolemia is less than the volume that causes signs of dyspnea in dogs and cats with hemothorax. Diagnosis of a clinically significant hemothorax, much like pneumothorax, is based on thoracocentesis. Oxygen support and vigorous volume expansion techniques are always indicated as part of the initial treatment strategy for dogs and cats with hemothorax. Thoracostomy tube placement and continuous pleural drainage is indicated when greater than 5 mL/kg of blood is retrieved from the pleural space. Continuous drainage allows quantification of ongoing blood loss, prevention of atelectasis, and autotransfusion of shed blood.

Figure 126-1 Pneumothorax. Note retraction of the lung from the chest wall, consolidation of lung lobes, and the appearance of the heart falling to the side of the atelectatic lobes.



126.1.3 Diaphragmatic Hernia

Diaphragmatic hernia is most common after blunt thoracic trauma and is thought to result from rapid compression of the abdomen with the majority of the force directed cranially against an open glottis.

Penetrating thoracic and abdominal injuries can also cause diaphragmatic hernia. The dog or cat with diaphragmatic hernia may not show clinical signs or may have dyspnea, decreased lungs sounds ventrally to diffusely, borborygmi on auscultation of the thorax, an "empty" abdominal palpation, or a combination thereof. Diaphragmatic hernia is commonly associated with pleural effusion. Some dogs and cats may develop clinical signs of diaphragmatic hernia months to years after the initial trauma. Oxygen support will be beneficial in the initial stabilization of animals with diaphragmatic hernia. In addition, positioning the pet with the chest slightly higher than the abdomen may promote movement of mobile abdominal viscera back into the abdomen. Diaphragmatic hernia may be suspected on physical examination but is confirmed through diagnostic imaging techniques (survey radiographs, positional radiographs, positive contrast peritoneography, upper gastrointestinal contrast study, ultrasound, or computed tomography). Diaphragmatic hernia is a surgical problem that necessitates elective repair as soon as the respiratory and cardiovascular systems have been stabilized. Indications for immediate surgical intervention include fever, small bowel obstruction, biliary obstruction, protracted vomiting or a distended stomach within the pleural space. In the latter clinical syndrome, transthoracic gastrocentesis or orogastric intubation are indicated prior to anesthesia to relieve signs of dyspnea. Prognosis for survival of dogs and cats with diaphragmatic hernia ranges from 50% to 90%.

126.2 TRAUMA-ASSOCIATED PULMONARY INJURIES

126.2.1 Pulmonary Contusion

Pulmonary contusion (PC) refers to lung lesions that occur after a compression-decompression injury. Subsequent hemorrhage and edema lead to alveolar collapse and lung consolidation. Hypoxemia results from ventilation: perfusion mismatch, shunt, diffusion impairment, and in severe cases, hypoventilation. Much like pneumothorax, pulmonary contusion is common after trauma. *All dogs that have sustained trauma have PC until proven otherwise*. If the veterinarian makes this assumption, they are more likely to identify important physical examination findings and make treatment decisions that will improve outcome. *The presence of clinically significant PC (severe enough to cause clinical signs) is a physical examination diagnosis*. On auscultation of the thorax, increased lung sounds distributed unevenly between the hemithoraces is most commonly recognized. However, exceptions include the presence of concurrent pleural space disease and complete lobar consolidation, both of which may result in decreased lung sounds. Coughing and hemoptysis may be seen in dogs with moderate to severe PC. Small animals with rib fractures or flail chest often have concurrent PC. Radiographic evidence of PC includes interstitial to alveolar infiltrates and lobar consolidation. Initial therapy for PC is oxygen support to maintain oxygen saturation >92%. Severity of PC can be quantified through arterial blood gas analysis and calculation of alveolar-arterial oxygen gradient and the PaO_2:FiO_2.

Treatment of PC is largely supportive. The cornerstones of therapy include oxygen delivery by cage, hood, or nasal cannulae to maintain SpO_2 greater than 92% on FiO_2<0.60 with-out severe increases in respiratory effort. Often overlooked is the importance of frequent changes in position of the animal. Standing and short walks may prevent and combat atelectasis. Positive pressure ventilation (PPV) is indicated if oxygenation or ventilation requirements cannot be met or if they can only be met with severe increases in respiration efforts. Fluid therapy in the animal with PC is challenging. Basic guidelines include maintainance of euvolemia in light of concurrent injuries, maintainance of hydration, and efforts to avoid fluid overload. Despite numerous opinions, there is no clear answer to the question of whether crystalloid or colloid therapy is most appropriate for dogs with PC. In a 1999 study by Powell et al, corticosteroids were not shown to decrease duration of hospitalization or need for oxygen support. Because PC is associated with increased vascular permeability, furosemide is unlikely to be of benefit unless iatrogenic fluid overload has taken place. Bronchodilators are unlikely to be of benefit because PC is not a reactive small airway disease, and antibiotics are not indicated because of the exceedingly low

incidence of bacterial pneumonia in dogs with PC. Prognosis for dogs with PC is based on severity of pulmonary injury but is generally good. Dogs that require positive pressure ventilation to maintain oxygenation and adequate ventilation have a more guarded prognosis.

126.3 TRAUMA-ASSOCIATED THORACIC WALL INJURIES

Thoracic wall trauma is most often associated with a host of concurrent thoracic injuries such as pneumothorax and pulmonary contusion.

126.3.1 Penetrating Thoracic Injury

Wounds to the thorax should be immediately covered with an occlusive sterile dressing. Following stabilization and management of concurrent injuries (pneumothorax) and radiography, the dog or cat should be placed under general anesthesia and the wounds explored. Simple probing is *not* adequate to determine whether or not wounds have penetrated the pleural space. Penetrating thoracic wounds should be explored, debrided, lavaged, cultured, and reconstructed with use of appropriate drainage techniques. Broad-spectrum antibiotic therapy is indicated to combat bacterial infection. Antibiotic therapy should be empirical based on likely contaminants while culture is pending. The external wound in animals with penetrating thoracic injury is often the "tip of the iceberg" and necessitates an aggressive, proactive approach to maximize the likelihood of a favorable outcome.

126.3.2 Rib Fractures and Flail Chest

Rib fractures happen with variable frequency after trauma and are diagnosed based on physical examination and/or thoracic radiography. Pain is the primary problem induced by rib fractures; however, penetration of the visceral pleura by a broken rib could result in pneumothorax and/or hemothorax. The chest wall is a resilient structure that requires significant force to cause a fracture. When such forces are applied across the thorax, intrathoracic injury is common. *Rib fractures are commonly associated with pulmonary contusion*. Pain associated with rib fractures can be controlled with regional anesthesia (narcotic epidural), systemic analgesics, or local intercostal blockade with bupivicaine (dogs: 0.75% solution diluted to 0.25% infiltrated as a small bleb caudal to the rib and dorsal and ventral to rib fractures; block single nerves cranial and caudal to the injured rib or segment; total dose should not exceed 1.5 mg/kg and extreme caution should be exercised so as not to compromise ventilation by blocking too many intercostal nerves). Flail chest refers to the fracture of multiple adjacent ribs in multiple locations, which creates a floating thoracic segment that moves paradoxically to the remainder of the chest wall. Flail chest is a diagnosis based on physical examination. The combination of pendulous airflow, underlying pulmonary trauma, concurrent pleural space injuries, and pain predispose to hypoxemia and hypoventilation. Treatment of flail chest should initially be directed towards pain control and management of concurrent thoracic injury (e.g., pulmonary contusion, pneumothorax, etc.). Surgical fixation of flail chest is frequently unnecessary. When needed, it should be performed after the animal is stable.

462
463

126.4 TRAUMA-ASSOCIATED MYOCARDIAL INJURY

126.4.1 Arrhythmias

Cardiac arrhythmias, most commonly of ventricular origin, are often diagnosed 12–36 hours after trauma. These arrhythmias, often referred to as "traumatic myocarditis" and "myocardial contusion," may result from direct injury to the heart but are more likely a result of transient decreased myocardial oxygen delivery resulting from shock, with subsequent ischemia and later reperfusion injury. Physical examination may reveal pulse

deficits, high pulse rate, and/or weak pulses. Severe arrhythmias may cause signs of shock. Common arrhythmias include isolated premature ventricular contractions, accelerated idioventricular rhythms, and ventricular tachycardia. Much debate exists as to when or if trauma associated ventricular arrhythmias need to be treated. Definite indications for treatment of ventricular arrhythmias include heart rate greater than 180 bpm, R on T phenomena, and any arrhythmia that is causing signs of decreased tissue perfusion. It is recommended that treatment be based on heart rates greater than 140 bpm, to decrease myocardial (and thus whole body) oxygen consumption. Prior to use of antiarrhythmic agents, blood pressure should be normalized (if possible), SpO_2 should be greater than 93%, and electrolyte and acid base status should be normalized. Subsequent treatment with lidocaine (2 to 4 mg/kg bolus followed by 50 to 80 μg/kg/min CRI in dogs) will abolish most ventricular arrhythmias. Refractory arrhythmias causing clinical signs of decreased perfusion of the tissues may be treated with procainamide. Most trauma-associated arrhythmias will resolve over 2 to 4 days.

126.4.2 Pericardial Effusion

Pericardial effusion is a rare complication of trauma in the dog and cat; however, it should be considered as a differential diagnosis in animals with clinical signs of shock. Clinically significant pericardial effusion should be suspected from physical examination findings and confirmed through echocardiographic assessment. Physical examination findings consistent with pericardial effusion include pale mucous membranes, slow capillary refill time, and muffled heart sounds, pulsus paradoxus (waxing and waning pulse pressure with respiratory cycle), and distended jugular veins. In the trauma situation, however, these physical examination findings may be complicated by concurrent injuries and hypovolemia. In this situation echocardiography is the most appropriate diagnostic test. Thoracic radiography may be helpful, but in acute pericardial effusion, the cardiac silhouette may not appear significantly enlarged although it may be more round than normal. Pericardial effusion should be relieved by pericardiocentesis.

126.5 TRAUMA-ASSOCIATED MEDIASTINAL INJURY

126.5.1 Pneumomediastinum

Pneumomediastinum is defined as an accumulation of air within the mediastinal space and, like rib fractures, should serve as a “flag” for concurrent injuries. Pneumomediastinum may result from injury to the large airways (see below), esophagus, alveoli (with subsequent tracking of air back into the mediastinum), and the cervical region. In the cervical region, air can track along the trachea and vascular structures of the neck into the mediastinum. Pneumomediastinum is rarely of clinical consequence but may be suspected in animals with subcutaneous emphysema in the cervical region. Pneumomediastinum can be definitively diagnosed on thoracic radiographs. An effort should be made to identify and definitively treat concurrent injuries.

126.5.2 Tracheal Avulsion

Tracheal avulsion is thought to occur due to a rapid and extreme hyperextension injury to the head or neck and is more common in cats than in dogs. Tracheal avulsion may affect the intrathoracic or extrathoracic trachea. Both intrathoracic and extrathoracic tracheal avulsion can be associated with subcutaneous emphysema, signs of respiratory distress, and airway obstruction on initial physical examination. Radiographic examination will illustrate pneumomediastinum and may or may not reveal discontinuity of the tracheal silhouette. Frequently, clinical signs will abate as the airway is maintained by a thin mediastinal reflection. However, within the following 1 to 2 weeks, dyspnea usually develops secondary to fixed airway obstruction as the ends of the

avulsed trachea begin to stenose. Subsequent radiographic evaluation will better illustrate lack of continuity of the tracheal silhouette. Treatment is surgical repair and reconstruction of the trachea.

127 CHAPTER • 127 Blood Transfusions, Component Therapy, and Oxygen-Carrying Solutions

Ann E. Hohenhaus

Important advances have occurred in veterinary transfusion medicine over the past 10 years due to an increased knowledge and expertise. The major innovation has been the advent of component therapy. Component therapy is considered the optimal method of transfusion since it allows specific transfusion therapy: red blood cells for anemia and plasma to provide deficient coagulation factors. The use of whole blood in anemic patients wastes the plasma, which could be used to control hemorrhage in a dog with anticoagulant rodenticide toxicity. A dog with anemia secondary to chronic renal failure does not require coagulation factor replacement and needs only a red blood cell transfusion. The plasma from this unit of blood can be used for a different dog with a bleeding disorder. By transfusing only the component required to treat the disorder, the risk of adverse reaction is decreased while efficacy is maintained.

Blood for the production of components is collected as whole blood in an anticoagulant preservative solution. The collection bag is sterilely manufactured and comprises multiple bags interconnected via sterile tubing. The whole blood collected into this system is processed through one or more centrifugation steps to produce the various blood components. Each component has a specific composition, storage requirement, and clinical use (Table 127-1). Blood components are the products typically available from veterinary blood banks (Table 127-2).

Table • 127-1 Blood Products Available from Veterinary Blood Banks

PRODUCT	CONTAINS	USES	DOSAGE*	REACTIONS
Whole blood	RBCs, WBCs, plasma, platelets, anticoagulant	Feline transfusions	10–20 mL/kg	Fever, acute hemolytic
		Hypovolemic anemia Pediatric transfusions		Volume overload
Packed red blood cells	RBCs	Clinically symptomatic anemia	6–10 mL/kg	Acute hemolytic, fever
Fresh frozen plasma	Plasma, anticoagulant	Coagulation factor deficiency	6–10 mL/kg	Volume overload, allergic, fever
	All clotting factors, immunoglobulins	Failure of passive transfer		
Frozen plasma	Plasma, anticoagulant	Failure of passive transfer	6–10 mL/kg	Volume overload, allergic, fever
	Low levels of clotting factors, immunoglobulins			
Cryoprecipitate	Factors VIII, XIII, vWF, fibrinogen	Deficiency of factors VIII, XIII, vWF, fibrinogen	1 unit/10 kg	Allergic, fever
Cryo-poor plasma	Factors II, IV, IX, X	Rodenticide intoxication	6–10 mL/kg	Allergic, fever
Platelet rich plasma	Platelets, plasma	Decreased platelet production	1 unit/10 kg	Allergic, fever
Frozen platelets	1×10^{11} platelets	Undefined	1 unit/10 kg	Bradycardia
	DMSO, plasma	ITP?		

* The dosage of any blood product is simply a guideline for the initial transfusion. All transfusions are given "to effect," which means that until the RBC count is high enough to adequately improve the recipient's oxygenation or adequate coagulation factors have been transfused to cor-rect the hemorrhagic process. *NA,* Not applicable.

To improve the ability of veterinarians to use blood components effectively, this chapter discusses the various components available for use in veterinary patients regarding their composition, clinical use, dosage, and most common adverse reactions. Although there have been many advances in veterinary transfusion medicine, there is currently not a consensus regarding the size of a "unit" of blood. For the purposes of this chapter, a unit of canine whole blood will be defined as the American Association of Blood Banks defines a unit of human blood (see Table 127-2). A unit of whole blood will be the blood (450 mL +/−45 mL) plus the anticoagulant (63 mL) collected from one dog into a standard blood bag. A "unit" of a component is the volume of product, for example, packed red blood cells or fresh frozen plasma obtained from 1 unit of whole blood. This information will not apply to blood from all blood banks, and the reader is referred to the specific product inserts for information regarding a particular blood bank's products. Because feline blood is collected in such a small volume (40 to 50 mL of whole blood per cat) and there is a lack of appropriate sized multi-bag systems, feline blood is not routinely processed into components, but it is possible to do so and feline components can be purchased from some veterinary blood banks.

464
465

Table • 127-2 Volume in Various Units of Canine Blood Products

COMPONENT	VOLUME OF BLOOD OR PLASMA	VOLUME OF ANTICOAGULANT	TOTAL VOLUME IN ONE UNIT
Whole blood in standard anticoagulant	405–495 mL	63 mL	468–558 mL
Packed red blood cells in additive solution	200–240 mL	100-mL additive solution	300–350 mL
Packed red blood cells	200–240 mL	NA	200–240 mL
Fresh frozen plasma	200–240 mL	NA	200–240 mL
Cryoprecipitate	60–70 mL	NA	60–70 mL
Cryo-poor plasma	~100 mL	NA	~100 mL
Platelet rich plasma	200–240 mL	NA	200–240 mL

When deciding to transfuse a patient with either a red blood cell product or a plasma product, the veterinarian must have in mind the goal of administering the transfusion. The veterinarian must recognize that transfusions do not cure any disease but merely supplements an absent or deficient component of blood on a temporary basis while the underlying disease is treated and the deficiency resolves. The decision to transfuse should always weigh the expected benefit to the patient against the risk of adverse effects of the therapy. To ensure safe administration of a transfusion, each patient who receives a transfusion will require pretransfusion testing, and monitoring during and after administration to prevent or recognize the side effects of that particular blood component.

127.1 RED BLOOD CELL PRODUCTS

Blood products that contain red blood cells include whole blood, packed red blood cells (pRBCs), pRBCs in additive solution, and leukoreduced pRBCs. The only indication for transfusion of a red blood cell containing component is a clinically symptomatic anemia (Table 127-3). Packed red blood cells, pRBC in additive solution, and leukoreduced pRBCs are appropriate products to treat anemia caused by blood loss, hemolysis, or bone marrow failure (see Table 127-3). Patients who are assymptomatic for their anemia do not need to be transfused, but an exact hemoglobin concentration or hematocrit level at which a red blood cell transfusion should be given has not been determined. Clinical signs of anemia that indicate red blood cell transfusion should be considered are tachycardia, weakness, tachypnea, and collapse. However, these clinical signs can also be attributed to many underlying diseases associated with anemia. The ability for physiologic mechanisms to compensate for a lack of red blood cells and the body's ability to produce red blood cells should be considered in the decision to transfuse. Because full compensation for anemia requires several days, a rapid onset of anemia from traumatic hemorrhage will require transfusion at a higher hemoglobin concentration or hematocrit than an anemia with a slow onset, such as pure red cell aplasia. Dogs or cats with pulmonary disease may require a transfusion at a higher hematocrit than

those without, since the compromise of the respiratory system will decrease oxygenation of hemoglobin. Concurrent cardiac disease may limit the compensatory increase in cardiac output in response to anemia and dogs and cats with significant cardiac disease may require a transfusion at a higher hemoglobin or hematocrit than those without cardiac disease. When the hemoglobin reaches 3 g/dL or the hematocrit 12%, the major organs have reached the limit in their ability to compensate for a lack of red blood cells and the need for red blood cell transfusion is urgent. Above that level of hemoglobin concentration or hematocrit, the requirement for transfusion becomes less urgent and the clinical status of the patient, the rapidity of decline of red blood cells and the ability of the bone marrow to replace the red blood cells must be weighed against the likelihood of adverse effects from transfusion.

Table • 127-3 Suggested Blood Components for Treatment of Various Anemias

TYPE OF ANEMIA	OPTIMAL COMPONENT	ALTERNATE COMPONENT	ALTERNATE COMPONENT
Blood loss anemia (hypovolemic)	Packed red blood cells and crystalloid or colloid solutions	HBOC	Whole blood
Blood loss anemia (normovolemic)	Packed red blood cells	HBOC	Whole blood
Anemia of chronic renal failure	Packed red blood cells	Whole blood	
Anemia of bone marrow failure	Packed red blood cells	Whole blood	HBOC
Hemolytic anemia	Packed red blood cells	HBOC	Whole blood

HBOC, Hemoglobin based oxygen carrier.

465

466

Pretransfusion testing prior to transfusion of a red blood cell containing component should include a blood type in every cat receiving a red blood cell transfusion. If a cat has not previously been transfused, a blood type is sufficient pretransfusion testing. Blood typing or cross matching a dog prior to the first transfusion is not necessary. In subsequent transfusions in both, dogs and cats, a cross match should be performed to determine compatibility of the red blood cells to be transfused.

The most serious adverse effect of administration of any red blood cell containing component is acute hemolytic transfusion reaction due to recipient antibodies against the donor red blood cells. The most common reaction, fever, is believed to be due to cytokines contained in the transfused blood or from antibodies against RBC, WBC, or platelets. As with any transfusion, there is a risk of volume overload, Type I hypersensitivity reactions causing facial edema, allergic reactions, vomiting, and fever.

Whole blood (WB) is blood collected from the donor, plus the anticoagulant. A standard blood bag contains 63 mL of anticoagulant. It is probably the most commonly used product in veterinary practice since it can be produced without any expensive equipment. Whole blood is typically used to transfuse cats. Feline units of blood are usually 40 to 50 mL of blood plus 5 to 9 mL of anticoagulant preservative solution. Ideally, WB should rarely be used in the dog since component therapy conserves blood and allows more dogs to be transfused from one unit of donated blood. WB would be most appropriate in pediatric transfusions when it would waste an entire unit of blood to open it for 10 or 20 mL to transfuse a small puppy. Whole blood would also be appropriate for exchange transfusions, in which the patient's blood is removed and replaced. In addition to supplying red blood cells, whole blood would replace clotting factors and albumin, which are removed in the exchange process. Whole blood could be used for patients who are experiencing hypovolemic anemia from hemorrhage, but packed red blood cells and crystalloid or colloid solutions will achieve the same effect.

Whole blood should not be used in normovolemic anemia because of the risk of volume overload from the additional volume plasma adds to the transfusion.

The initial dosage of WB is 10 to 20 mL/kg.

Packed red blood cells are the cells and a small amount of plasma remaining after the plasma and anticoagulant is removed. The PCV is approximately 80%, which makes pRBC very viscous. Normal (0.9%) saline is the only solution that should be added to any blood product and can be done with pRBC to improve flow.

The initial dosage of packed red blood cells is 6 to 10 mL/kg. Packed red blood cells in additive solution are processed similarly to pRBCs, but after the red blood cells are separated from the plasma, 100 mL of an additive solution are added to the red blood cells. PCV is 55% to 60%. Additive solution contains dextrose, adenine, mannitol, and sodium chloride preserving the red blood cell function longer than the traditional anticoagulants ACD or CPDA (35 to 37 versus 21 days). It eliminates the need to add saline to the pRBC to decrease viscosity and improve flow. The fresh frozen plasma obtained from this process is identical to FFP produced from standard anticoagulant bags. This blood product is administered exactly the same as pRBCs.

The initial dosage of pRBCs in additive solutions would be 10 to 15 mL/kg.

Leukocyte-reduced packed red blood cells are produced from whole blood via centrifugation in the same manner as standard packed red blood cells, but an additional processing step is used to remove the white blood cells. Removal of 99.9% of white blood cells is accomplished by passing the blood between the collection bag and an accessory bag via an integral filter. Filtration can be performed at the time of blood collection or immediately prior to transfusion. White blood cells are removed because they have been implicated as a cause of certain types of transfusion reactions. Filters are designed to remove white blood cells without decreasing red blood cell biochemical characteristics, viability, storage time, or PCV.

The major reaction to leukocyte reduced pRBCs is an acute hemolytic transfusion reaction. The risks of non-hemolytic fever, transfusion transmitted infections, immunosuppression, and alloimmunization should be decreased with leukocyte reduction. This blood product is administered exactly the same as pRBC.

The initial dosage of leukocyte reduced pRBC would be 15 mL/kg.

127.2 PLASMA COMPONENTS

Fresh frozen plasma (FFP) is the plasma obtained from WB, which has been centrifuged, and the red cells removed within 6 hours of collection (Table 127-4). The anticoagulant remains in the plasma fraction during processing. When it is frozen at −20°C, the clotting factors maintain activity for 1 year. FFP is an excellent source of clotting factors and can be used to treat a wide variety of hemorrhagic disorders, including hemophilia, von Willebrand's disease, rodenticide intoxication, and disseminated intravascular coagulation. It is not a good source of albumin or nutrition, and calculations indicate 45 mL/kg would be required to increase the serum albumin concentration by 1 g/dL. FFP may be used in puppies or kittens with failure of passive transfer. Plasma transfusions may cause volume overload or allergic reactions. Blood typing before administration of a plasma transfusion is required in cats because antibodies contained in the plasma will cause a transfusion reaction if plasma incompatible with the recipient's red blood cells is administered.

The initial dosage of FFP is 6 to 10 mL/kg one to three times daily. The dosage depends on the condition being treated. In kittens with failure of passive transfer, a dose of 150 mL/kg of serum SC or IP has raised serum IgG to normal levels. A dose of 22 to 40 mL/kg of serum has been recommended in puppies with passive transfer, but normalization of IgG levels was not attained. Plasma can be used in place of serum.

Frozen plasma (FP) is plasma that has not been processed and frozen within 6 hours of collection or fresh frozen plasma stored at−20°C for more than 1 year. Both contain reduced levels of labile coagulation factors V and VIII. It may also be produced from WB stored more than 6 hours. Frozen plasma may be used in puppies or kittens with failure of passive transfer. Albumin is preserved at that temperature for 5 years and frozen plasma may be used as a source of albumin.

The initial dosage of FP is 6 to 10 mL/kg one to three times daily depending on the condition being treated.

Cryoprecipitate is a concentrated source of von Willebrand's factor, fibrinogen (factor I), and factor VIII prepared from 1 unit of FFP. Fresh frozen plasma is thawed at 4°C. During thawing, a white precipitate (cryoprecipitate) forms in the plasma and this precipitate contains vWf, factors VIII and I. The cryoprecipitate is separated from the liquid plasma by centrifugation. The liquid plasma is termed cryo-poor plasma. Cryoprecipitate is used to treat von Willebrand's disease, hemophilia A, and fibrinogen deficiency. Storage and handling of cryoprecipitate is similar to fresh frozen plasma. It can be stored at−20°C for 1 year. Like any plasma component, cryo-precipitate may cause allergic reactions. One unit of cryoprecipitate is the amount produced from 1 unit of FFP.

The initial dosage of cryoprecipitate is 1 unit per 10 kg of body weight.

Cryo-poor plasma is the plasma that remains after the cryo-precipitate is removed. Cryo-poor plasma contains factors II, VII, IX, and X, which make it useful for the treatment of rodenticide intoxication. Storage and handling of cryo-poor plasma is similar to fresh frozen plasma. Like any plasma component, cryo-poor plasma may cause allergic reactions.

466
467

Table • 127-4 Suggested Blood Components for Treatment of Various Coagulopathies

TYPE OF COAGULOPATHY	OPTIMAL COMPONENT	ALTERNATE COMPONENT
Anticoagulant rodenticide intoxication	Fresh frozen plasma	Cryo-poor plasma
Disseminated intravascular coagulation	Fresh frozen plasma	
Von Willebrand's disease	Cryoprecipitate	Fresh frozen plasma
Hemophilia A Factor VIII deficiency	Cryoprecipitate	Fresh frozen plasma
Hemophilia B Factor IX deficiency	Fresh frozen plasma	
Liver disease coagulapathy	Fresh frozen plasma	

The initial dosage of cryo-poor plasma is 1 unit per 10 kg of body weight.

Platelet-rich plasma (PRP) is prepared from fresh whole blood by centrifugation at a slower centrifuge rate than for production of pRBC and plasma. The platelets are suspended in plasma to facilitate transfusion and transfused within hours of collection. PRP should not be refrigerated as it inactivates platelet function. Allogeneic platelet transfusions should be most useful in cases of decreased platelet production rather than cases of increased consumption or destruction of platelets. Unfortunately, increased destruction of platelets is the most common cause of thrombocytopenia in the dog. Platelet transfusions may cause allergic reactions or fever. Multiple platelet transfusions may result in alloimmunization and refractory thrombocytopenia.

The dosage is 1 unit of platelets via PRP per 10 kg of body weight.

127.2.1 Other Blood Components

Frozen platelets are collected through plateletpheresis. Platelets are preserved by DMSO and also contain a small amount of fresh frozen plasma. Efficacy data on this product has not been published, but immune-mediated thrombocytopenia is the recommended target disease for this product. Because the product contains DMSO, it must be infused slowly or bradycardia will result. The dosage is 1 unit of platelets per 10 kg of body weight. The product insert indicates this dose should increase the platelet count 20,000/μL when measured 1 to 2 hours post transfusion.

Human immunoglobulin is a concentrated source of immunoglobulin produced from the plasma of more than 1000 human donors via ethanol cold fractionation technique. In a limited number of cases, it has been used to treat acute canine immune-mediated hemolytic anemia (IMHA). Human immunoglobulin has also been used to treat immune-mediated thrombocytopenia in humans and cutaneous drug reactions in a dog and a cat. It is believed that providing the large number of immunoglobulin molecules overwhelms the reticuloendothelial system and prevents it from destroying additional red blood cells. Immunoglobulin may also neutralize or modulate pathogenic autoantibodies and modulate activation and cytokine production. Immunoglobulin therapy of dogs with IMHA has been associated with thrombosis and thrombocytopenia, but these abnormalities may be a result of the primary disease not the immunoglobulin infusion. Theoretically, repeat administration could cause severe anaphylactic shock, but no reports of a second infusion have been published. The recommended dosage is 0.5 to 1 g/kg and the reconstituted product is infused over 6 to 8 hours.

127.3 OXYGEN-CARRYING SOLUTIONS

The term *blood substitute* is a poor description of intravenous solutions designed to deliver oxygen to the tissues as an alternative to homologous red blood cells. These solutions substitute for only one function of blood, the ability to carry oxygen; therefore they are used to treat patients with anemia from blood loss, hemolysis, or bone marrow failure. They do not contain coagulation factors, platelets, or white blood cells and consequently cannot perform the functions associated with those elements of blood. There are 2 major types of oxygen-carrying solutions: perflurocarbon emulsion-based carriers, and hemoglobin-based oxygen carriers (HBOC). Currently, the majority of the products are under clinical investigation in humans and the only product approved for use in veterinary patients is an HBOC.

HBOC-201 (Oxyglobin, Biopure Corporation, Cambridge, MA) differs from red blood cells in several ways. It is an acellular hemoglobin clear, dark purple solution with a pH of 7.8, produced from purified bovine hemoglobin. Oxyglobin contains 13 g/dL polymerized hemoglobin in a modified lactated Ringer's solution. It has an osmolality of 300 mOsm/kg.

Because Oxyglobin contains no red blood cells, the hemoglobin polymers transport oxygen in the plasma. Oxyglobin increases oxygen carrying capacity without increasing red blood cells; consequently, the PCV does not rise in patients who receive Oxyglobin and patient monitoring must include a measurement of total (RBC +plasma) hemoglobin to fully assess oxygen carrying capacity. Not all hematology analyzers measure hemoglobin concentration and only those that measure hemoglobin should be used to assess the effect of Oxyglobin. Hemoglobin can readily be measured using a hemoglobin meter, HemoCue, (HemoCue, Inc., Mission Viejo, CA), which has been validated in veterinary patients and uses a modified azide methemoglobin reaction to measure hemoglobin. The Hemavet multispecies analyzer (CDC Technologies, Oxford, CT), impedance analyzers and flow cytometric analyzers measure hemoglobin. I-Stat (Sensor Devices, Inc., Waukesha, WI) and IRMA Blood

Analysis System (Diametrics Medical, Saint Paul, MN) calculate hemoglobin and should not be used to measure the effect of Oxyglobin.

Although polymerization of hemoglobin molecules prolongs the half-life in the plasma over that of native hemoglobin ($t_{1/2}$ =18 to 43 hr, at a dose of 10 to 30 mL/kg), the half-life of Oxyglobin is shorter than that of transfused allogeneic red blood cells, (days to weeks). Oxyglobin is labeled to increase oxygen-carrying capacity when compatible canine blood is not available due to inadequate supply or serologic incompatibility. It has a 36-month shelf life without refrigeration, and there is no requirement for preinfusion blood typing or crossmatching since antigenic red blood cell membranes are removed during ultrapurification.

467
468

Adverse effects differ from red blood cell–containing components. The intense purple color of the solution temporarily imparts an abnormal color to mucous membranes and urine. Fortunately, the discoloration does not affect oxygen saturation monitoring via pulse oximetry. The presence of Oxyglobin in plasma also limits laboratory testing, especially when colorimetric methodology is used. Tests most commonly affected are bilirubin, liver enzymes, creatinine, glucose, urine dipstick measurements, but the effect varies with the equipment used and the concentration of Oxyglobin in the plasma or urine. Oxyglobin is currently labeled as a single dose product, because there are concerns about the antigenicity of bovine hemoglobin in non-bovine species, but to date, antibodies do not appear to result in anaphylactic or anaphylactoid reactions in dogs administered multiple doses of the product. The large polymers of hemoglobin exert an oncotic effect in the plasma, which results in volume expansion. Parameters such as central venous pressure, respiratory rate, and respiratory sounds should be monitored during and following an Oxyglobin infusion to prevent volume overload, pulmonary edema, and pleural effusion.

The manufacturer's recommended dosage is 10 to 30 mL/kg administered as a continuous intravenous solution in dogs. Typically, the low end of the dose range is used for the initial infusion. If required, the remaining dose can be infused. Oxyglobin has not been approved for use in cats and the optimal dose and rate of infusion have not been determined in cats, although Oxyglobin has been administered safely to cats.

128 CHAPTER • 128 Blood Pressure Assessment

Rebecca L. Stepien

Routine assessment of blood pressure (BP) in clinical veterinary patients is a relatively recent development, and the volume of published literature regarding what is normal and abnormal in pet dogs and cats is growing rapidly. In contrast to human hypertension (HT), hypertension in veterinary patients most often is associated with a causative underlying disease[1–4] (Table 128-1). BP values obtained during diagnostic evaluation are assessed in conjunction with other clinical findings (e.g., evidence of retinal detachment, a history of polyuria and polydipsia), because these associated findings may point to the cause of the HT or indicate HT-associated end-organ damage. A single high BP value should never be used to diagnose systemic HT in the absence of other clinical information.

BP measurements that exceed published normal ranges are not always indicative of disease. Patient distress[5] or physical manipulations, such as fluid administration, may elevate BP acutely. The degree of clinical concern associated with elevated BP is proportional to the degree of elevation in combination with the clinical signs and clinical condition of the patient.

128.1 DEFINITION OF NORMAL

Normal ranges for BP in dogs[6–9] and cats[4,10–12] are often expressed as a mean value for a normal population ±2 standard deviations; animals with BP values outside this range are considered abnormal. The drawbacks to this approach to diagnosis of HT include inadvertent inclusion of normal animals with a BP value outside the "95% range" (leading to unnecessary diagnostic testing or therapy) or exclusion of HT as a diagnosis in an affected animal with mild or moderately elevated values (increasing the risk of end-organ damage). In addition, a dichotomous "normal" versus "too high" diagnostic result cannot take into account the differing risk of end-organ damage with increasing BP values.

Table • 128-1 Diseases/Clinical Findings Commonly Associated with Systemic Hypertension in Dogs and Cats*

DOGS	CATS
Ocular findings consistent with hypertensive choroidopathy, hypertensive retinopathy or intraocular hemorrhage	Ocular findings consistent with hypertensive choroidopathy, hypertensive retinopathy or intraocular hemorrhage
Chronic or acute renal failure	Chronic or acute renal failure
Hyperadrenocorticism	Hyperthyroidism
Diabetes mellitus	Diabetes mellitus
Neurologic signs unexplained by other causes	Any neurologic signs
Pheochromocytoma	Age ≥10 years
Unexplained left ventricular hypertrophy	Murmurs gallop rhythm
	NOTE: Idiopathic hypertrophic cardiomyopathy cannot be diagnosed without excluding hypertension.

* A complete funduscopic examination and BP measurement are indicated in animals known to have or suspected of having these disease conditions. Conditions that are rare in the species (e.g., hyperthyroidism in dogs) are not included. BP measurement is often included in routine cardiac evaluations.

Another approach to the diagnosis of HT is based on establishing diagnostic "cutoff" values at the level usually associated with clinically detectable disease. Clinical information regarding the BP typically associated with ophthalmologic[13] and renal[2,4,11] abnormalities in spontaneous canine and feline HT is available, but there is no information about threshold BP values for end-organ damage in this group of patients. Furthermore, the "trigger point" at which elevated BP results in clinical signs likely differs from patient to patient and may be affected by the rapidity with which the HT develops.[14]

Previous definitions of the high end of normal for dogs varied between 160 and 180 mm Hg and between 160 and 200 mm Hg in cats, but progression of renal damage in dogs is already enhanced with systolic BP (SBP) values in this range,[15] and clinical studies have documented end-organ damage at SBP values as low as 170 mm Hg.[13] Accordingly, current recommendations consider a SBP greater than or equal to 160 mm Hg (as measured by oscillometric or Doppler ultrasonographic methods) worthy of further diagnostic concern in both dogs[16] and cats,[17] although the use of antihypertensive medications may not be warranted (Table 128-2). The prevalence and importance of diastolic HT in dogs and cats are not well defined, therefore most recommendations for BP assessment relate to systolic BP measurement.

Table • 128-2 Recommended Approach to Assessment of Abnormal Blood Pressure Values

PATIENT STATUS	BLOOD PRESSURE (mm Hg)	RISK OF END-ORGAN DAMAGE	RECOMMENDED ACTION*
Clinical signs of hypertension (HT): Known underlying disease	≥180/120	High	Begin anti-HT medication prior to full evaluation of underlying disease conditions. Treat underlying disease.
	160–179/100–120	Moderate	Begin anti-HT medication prior to full evaluation of underlying disease conditions. Treat underlying disease.
	150–159/95–100	Low	Begin anti-HT medication prior to full evaluation of underlying disease conditions. Treat underlying disease.
	<150/95	Minimal	Treat underlying disease. Search for other causes of clinical signs (e.g., coagulopathy). If no other cause of signs is found, monitor BP over time.
Clinical signs of HT present No known underlying disease present	≥180/120	High	Begin anti-HT medication prior to full evaluation of underlying disease conditions. Perform diagnostic evaluation for underlying disease.
	160–179/100–120	Moderate	Begin anti-HT medication prior to full evaluation of underlying disease conditions. Perform diagnostic evaluation for underlying disease.
	150–159/95–100	Low	Consider anti-HT medication prior to full evaluation of underlying disease conditions. Perform diagnostic evaluation for underlying disease. Search for other causes of clinical signs (e.g., coagulopathy).
	<150/95	Minimal	Search for other causes of clinical signs (e.g., coagulopathy), If no other cause of signs is found, monitor BP over time.
No clinical signs of HT present	≥180/120	High	Treat underlying disease. Begin anti-HT medication.
At risk due to concurrent disease	160–179/100–120	Moderate	Treat underlying disease. Consider anti-HT medication if rapid resolution of underlying disease is not anticipated.
	150–159/95–100	Low	Treat underlying disease.

			Monitor BP every 3–6 months for progression.
	<150/95	Minimal	Treat underlying disease. Monitor BP every 3–6 months for progression.
Clinically healthy	≥180/120	High	Confirm BP value by repeated testing. If values are consistent, consider therapeutic trial of anti-HT medication.†
	160–179/100–120	Moderate	Confirm BP value by repeated testing. If values are consistent, monitor BP every 3–6 months for progression or development of clinical signs or compatible disease.
	150–159/95–100	Low	Confirm BP value by repeated testing. If values are consistent, monitor BP every 3–6 months for progression.
	<150/95	Minimal	Normal No further testing is indicated.

* The clinical course of action should be tailored to the individual patient's circumstances. Recommendations may change as more clinical information becomes available.

† The normal BP range for healthy sight hounds may be higher than for other breeds.[20]

471

472

128.2 APPROACH TO PATIENT GROUPS

The goals of detection of HT in cats and dogs are to alleviate clinical signs and to prevent future clinical signs or subclinical deterioration of organ function. Veterinary clinicians are at a disadvantage in the early detection of clinical signs of HT. In humans, stage 1 and stage 2 HT (BP values of 140–179/90–109 mm Hg) are frequently asymptomatic. When symptoms are reported, they often include patient perceptions that would be difficult to assess in veterinary patients, including morning headaches, a sense of fullness in the head, or "general unease"[18]. Similar BP, however, values have been associated with progression of renal damage in dogs with renal failure.[15] Because the first clinical sign of HT in dogs and cats may be catastrophic (e.g., retinal detachment), detection of BP elevations below the level likely to produce clinical signs is preferable. Therefore, except for in patient with overt clinical signs, detection of HT is a preventive measure. BP values are obtained using accurate and repeatable methodology (see Diagnostic Blood Pressure Measurement, Chapter 76). Persistent elevation of BP is a clinical finding that leads to further clinical investigation and to consideration of therapy.

128.3 PATIENTS WITH CLINICAL SIGNS OF HYPERTENSION

Hypertension has been documented in association with clinical abnormalities of the ocular, neurologic, cardiovascular, and renal systems,[13,19,20] and effective therapy of HT in these circumstances typically eases, if not resolves, clinical signs.[13] Animals with clinical signs of HT and elevated BP should receive immediate antihypertensive therapy to decrease BP and thereby alleviate clinical signs. A detailed evaluation for known causes of HT in the species in question follows acute antihypertensive therapy. In some cases, gaining control of

the underlying disease (e.g., pheochromocytoma, hyperadrenocorticism) may result in lowering or normalization of BP.

128.4 PATIENTS AT RISK FOR HYPERTENSION

Patients considered at risk for HT are those with no clinical signs of HT that have a disease condition or clinical signs of a disease known to be associated with HT in that species. Even though little reliable information is available on the effect of the duration of BP elevation and the extent of end-organ damage in spontaneous canine and feline HT, it is likely that with the exception of acute, extreme BP elevations, chronic BP elevations are more damaging to end-organ vascular beds than short-term elevations. Therefore early detection of elevated BP in dogs and cats at risk is aimed at detecting and managing any treatable underlying conditions and at attempting to maintain BP within a range less likely to lead to end-organ damage (see Table 128-2).

128.5 APPARENTLY HEALTHY PATIENTS

The prevalence of HT in apparently healthy dogs is low,[21] and oscillometric and Doppler ultrasonographic test methods are moderately sensitive and specific at a diagnostic SBP cutoff value of 160 mm Hg.[16] These test characteristics result in a low positive predictive value for abnormal test results in healthy dogs. Therefore, based on current information, routine screening of BP in this population is not recommended. The prevalence of HT in the healthy feline population is also low,[10] but the prevalence of renal disease and hyperthyroidism (both diseases commonly associated with feline HT) in older cats is high enough to prompt consideration of routine screening of cats over the age of 10 years.[13,17]

BP assessment is a diagnostic test indicated in patients likely to have HT and as part of preventive medical care in patients at risk. Aspects of BP assessment that may change over time include the degree of BP elevation leading to clinical concern and possibly intervention, the importance placed on systolic versus diastolic HT, and the selection of patient groups to be included in screening procedures.

129 CHAPTER • 129 Pathophysiology of Systemic Hypertension

Scott A. Brown

Systemic arterial blood pressure (BP) is the product of cardiac output and total peripheral resistance. Cardiac output may be further factored as the product of heart rate and stroke volume, yielding the following relationship:

$$\text{BP} = (\text{Heart rate} \times \text{Stroke volume}) \times \text{Total peripheral vascular resistance}$$

Thus any factor or process that persistently elevates one or more of these three determinants of BP can cause systemic hypertension. Similarly, to be effective, antihypertensive therapy must target one of the three determinants of BP.

Systemic hypertension can be simply defined as persistently elevated BP. Systemic hypertension is often defined on the basis of BP measurements in human beings as a systolic BP (SBP) greater than 140 mm Hg and/or a diastolic BP (DBP) greater than 90 mm Hg. In dogs and cats the definition of systemic hypertension is controversial, although one definition that applies to cats and most breeds of dogs is a SBP greater than 160 mm Hg and/or a DBP greater than 100 mm Hg in repeated, reliable measurements of BP in a calm animal.

The term *isolated systolic* (and *diastolic*) *hypertension* refers to a condition in which only the SBP (or DBP) persistently exceeds the corresponding normal range. In the past physicians were more concerned about elevation of the DBP, but recent studies suggest that end-organ damage, particularly renal, is better correlated with the degree of SBP elevation. Isolated systolic hypertension is common in elderly people as the result of a loss of arterial compliance, which develops as arterial walls stiffen with age. Although isolated systolic and diastolic hypertension is observed in dogs and cats, the prevalence and importance of these findings have yet to be well studied in veterinary medicine.

129.1 CLASSIFICATION SYSTEM

Systemic hypertension is often classified on the basis of causation as either primary (essential) or secondary. *Essential hypertension* exists when BP is persistently elevated even though a careful diagnostic evaluation fails to identify a cause of the hypertension. *Secondary hypertension* occurs when there is a known cause, generally a disease process that alters renal or neurohormonal functions. A clinical definition of essential hypertension is persistent elevation of BP in an animal with no clinical or biochemical evidence of a renal or endocrinologic abnormality that could cause hypertension (e.g., hypercorticism, hyperthyroidism, pheochromocytoma, hyperaldosteronism, or diabetes mellitus). Because of the broad normal ranges for creatinine and blood urea nitrogen (BUN) levels, the absence of azotemia is a necessary, but not sufficient, condition to eliminate renal disease as a cause of secondary hypertension in a dog or cat. Only a normal urinalysis, normal glomerular filtration rate (GFR), and normal renal biopsy can achieve this purpose. Essential hypertension accounts for 95% of cases of hypertension in human beings but has rarely been identified in dogs and has not been conclusively reported in cats.

Although used for decades in human beings, this primary (essential) versus secondary terminology is overly simplistic and misleading. As noted above, the BP cannot be elevated unless stroke volume, heart rate, and/or peripheral vascular resistance are increased (i.e., something must be abnormal). More important, the normal long-term renal response to systemic hypertension is natriuresis and diuresis, which should normalize the BP by reducing extracellular fluid volume and cardiac output. Therefore BP cannot remain persistently elevated without

an abnormality in renal sodium handling. Indeed, the kidney must play a causal or permissive role in any animal with systemic hypertension. At the very least, a functional kidney "disease" exists in every chronically hypertensive animal, regardless of whether the animal has essential or secondary hypertension. Nonetheless, it is important in the clinical evaluation of every hypertensive animal that an exhaustive search be made for an inciting cause of the increase in BP. This distinction between primary (essential) and secondary hypertension suggests and facilitates that search; for this reason, this terminology remains useful for clinical purposes.

129.2 GENESIS OF HIGH BLOOD PRESSURE

Because essential hypertension is rare in veterinary medicine, yet accounts for 95% of cases of identified hypertension in human beings, it might be expected that systemic hypertension is uncommon in veterinary medicine. To the contrary, diseases associated with secondary hypertension are quite common in certain veterinary species. In particular, chronic renal disease is frequently observed in geriatric cats and dogs, with the prevalence reaching nearly one in three cats in select populations. Because kidney disease is often associated with disturbances of neuroendocrine factors and body fluid balance, it is not surprising that most, although not all, surveys have identified systemic hypertension in a significant proportion of cats and dogs affected with kidney disease. Other examples of conditions associated with the development of secondary hypertension in dogs and cats include diabetes mellitus, hyperadrenocorticism, pheochromocytoma, and hyperthyroidism.

Systemic hypertension can arise from an excess of circulating glucocorticoids, caused by adrenocortical overproduction or exogenous administration. These compounds have a variety of effects, including a mineralocorticoid type, which stimulates renal retention of salt and water and resultant increases in blood volume and cardiac output. These animals also may suffer from overproduction of renin, which elevates peripheral vascular resistance, contributing further to the development of hypertension. Animals with diabetes mellitus similarly may develop systemic hypertension as a result of overproduction of renin and blood volume expansion associated with hyperglycemia.

Hyperthyroidism is relatively common in geriatric cats and is associated with increases in BP. Thyroid hormone enhances cardiac function and sensitivity of the myocardium to catecholamines. The result is tachycardia and increased stroke volume, resulting in systemic hypertension. It remains unclear whether hyperthyroid cats with systemic hypertension often, or always, have kidney disease as a contributing factor to the high BP.

Pheochromocytomas are rare tumors of the neuroendocrine cells of the adrenal medulla in which overproduction of epinephrine and norepinephrine leads to peripheral vasoconstriction, tachycardia, and an increase in stroke volume. Often the release of hormones is episodic, causing periodic "attacks" of tachycardia and hypertension.

A variety of medications may also produce secondary hypertension. Examples include corticosteroids (as noted above), cyclosporin A (vasoconstriction leading to increased peripheral vascular resistance), phenylpropanolamine (increased peripheral vascular resistance from alpha adrenergic effects), and erythropoietin (increased blood viscosity, which enhances peripheral vascular resistance).

The role of dietary factors in the causation of secondary hypertension is unclear in veterinary medicine. A segment of the human population and certain strains of rats exhibit sensitivity of BP to changes in dietary salt intake. However, most studies indicate that the BP of dogs and cats is salt insensitive unless the salt intake is massive or there is a pre-existing cause of secondary hypertension. However, sodium chloride (NaCl)-rich therapeutic agents can raise BP, particularly intravenous fluid and electrolyte solutions. Maintenance fluid administration with isotonic electrolyte solutions generally provides 250 to 500 mg NaCl/kg body weight/day, compared with a typical dietary intake of 25 to 50 mg NaCl/kg body weight/day. Overzealous fluid therapy, therefore, can contribute to or

cause systemic hypertension in susceptible patients. Any animal with systemic hypertension or a condition known as a possible secondary cause of hypertension (e.g., renal disease) should be considered potentially salt sensitive.

Ingestion of dietary omega-3 polyunsaturated fatty acids appears to be antihypertensive in human beings, but this may not be the case in dogs, in which these fatty acids' vascular effects appear to be intrarenal rather than systemic. Little is known about the vascular or intrarenal effects of dietary omega-3 polyunsaturated fatty acids in cats.

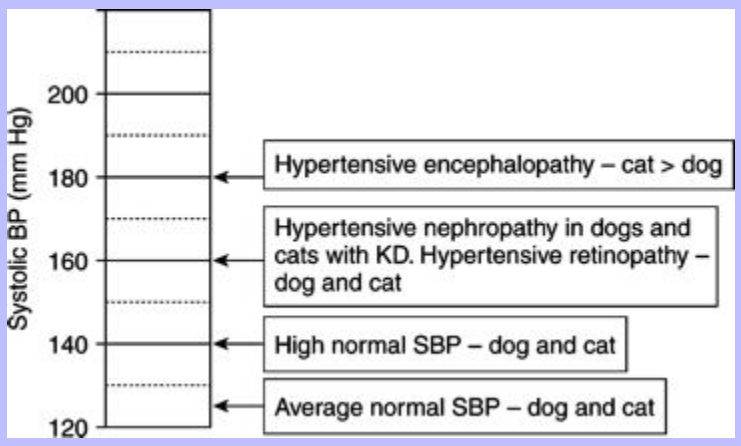
129.3 CONSEQUENCES OF SYSTEMIC HYPERTENSION

Unfortunately, systemic hypertension is usually asymptomatic initially and may go unrecognized for months or years until irreversible tissue damage becomes evident as organ failure ensues. Systemic hypertension in human beings is associated with complications in the cardiovascular system (e.g., myocardial infarctions, “strokes”), central nervous system (e.g., hypertensive encephalopathy, “strokes”), urinary system (e.g., progressive renal damage) and eyes (e.g., retinal and choroidal injury). In veterinary medicine, hypertension is recognized with increasing frequency in cats and dogs, where it has been linked to damage in these same tissues. Although this remains somewhat speculative, and some breeds of dogs (especially sight hounds) have unusually high normal ranges for BP, data are accumulating that suggest that cats and most breeds of dogs with systemic hypertension (systolic BP equal to or greater than 160 mm Hg) are at risk for adverse effects (Figure 129-1). The most commonly identified adverse effects of marked systemic hypertension occur when the systolic BP exceeds 180 mm Hg, especially if an acute rise in the SBP of 30 mm Hg or more occurs within 48 hours; these complications include hypertensive retinopathy (intraocular hemorrhage, retinal edema, and/or retinal detachment in cats and dogs), hypertensive encephalopathy (progressive stupor, coma, and seizures associated with intracranial edema), and central nervous system (CNS) “stroke” (uncommon in dogs and cats). At a somewhat lower BP (SBP of 160 to 180 mm Hg), chronic changes induced by hypertensive damage to the kidney, eye, and cardiovascular system are also recognized in dogs and cats; the threshold for this injury is not certain but lies at approximately 160 mm Hg in cats and most breeds of dogs.

473

474

Figure 129-1 Proposed thresholds for end-organ damage in dogs and cats with systemic hypertension (see text for details).



129.4 CARDIOVASCULAR EFFECTS OF HYPERTENSION

The most commonly observed effect of hypertension in the cardiovascular system is left ventricular hypertrophy. Cardiac muscle responds to chronically increased afterload by concentric hypertrophy (increased wall thickness without dilatation). Although left ventricular stiffness and reduced diastolic filling can elevate left ventricular diastolic pressure, leading to pulmonary congestion, this is uncommon. Functional failure (congestive heart failure) is also uncommon as a sequela of hypertension in dogs and cats unless a pre-existing or additional cardiovascular abnormality is present. Left ventricular hypertrophy may be documented clinically by thoracic radiography or cardiac ultrasonography. Effective antihypertensive therapy may reverse some of these changes.

A variety of vascular changes are observed in people with chronic hypertension. High pressures in small arteries and arterioles leads to extravasation of plasma into the vessel wall, producing a thickening referred to as *hyaline arteriosclerosis*. Chronic hypertension also induces vascular smooth muscle hypertrophy. Elderly human beings develop arteriosclerosis with a loss of large artery compliance and elasticity with aging. However, these vascular changes are seemingly absent or mild in dogs and cats, because they are seldom documented in these species.

129.4.1 Central Nervous System Effects of Hypertension

Circulation to the brain is generally well regulated locally, resulting in the property of *autoregulation*. This autoregulatory control of blood flow across a range of BP is mediated primarily by arteriolar smooth muscle, which constricts in response to a rise in BP (Figure 129-2). This protects the central nervous system from many of the adverse effects of systemic hypertension across a broad range of BP. However, there is a limit to the ability of these arterioles to prevent the transmission of elevated BP to the local microcirculation (i.e., arterioles, capillaries, and venules). Further rises in BP above this autoregulatory limit lead to increases in pressure and flow within the microcirculation, which alters Starling forces across the capillary wall. The subsequent rise in intracapillary hydrostatic pressure, in particular, tends to increase transcapillary fluid filtration, promoting the development of interstitial edema within the brain parenchyma. Because the brain is "compartmentalized" within the bony cranium, this increase in interstitial volume can lead to a rise in intracranial pressure, causing neurologic dysfunction referred to as *hypertensive encephalopathy*. Clinical signs caused by brain edema may include disorientation, head pressing, ataxia, stupor, coma, and seizures. If severe, edema-induced increases in intracranial pressure can lead to cerebral herniation under the tentorium or cerebellar herniation through the foramen magnum. Brain herniation is generally a fatal complication of hypertensive encephalopathy. Although this condition occurs in both species, for poorly understood reasons, cats are particularly susceptible to the development of hypertensive encephalopathy.

Hypertension may also lead to small artery rupture and resultant localized ischemia ("stroke" or cerebrovascular accident [CVA]), but this is uncommon in veterinary species, perhaps because medium and large vessel disease (atherosclerosis and arteriosclerosis, respectively) are relatively uncommon. A CVA can occur as a result of small artery rupture within the cerebral vasculature (hemorrhagic CVA) or from vessel thrombosis (thrombotic CVA). In both cases, affected portions of the brain suffer infarction, and the animal may exhibit clinical signs such as ataxia, disorientation, seizure, stupor, or coma. These occur in hypertensive patients in veterinary medicine but seem to be less common than hypertensive encephalopathy, particularly in cats.

129.5 OCULAR EFFECTS OF HYPERTENSION

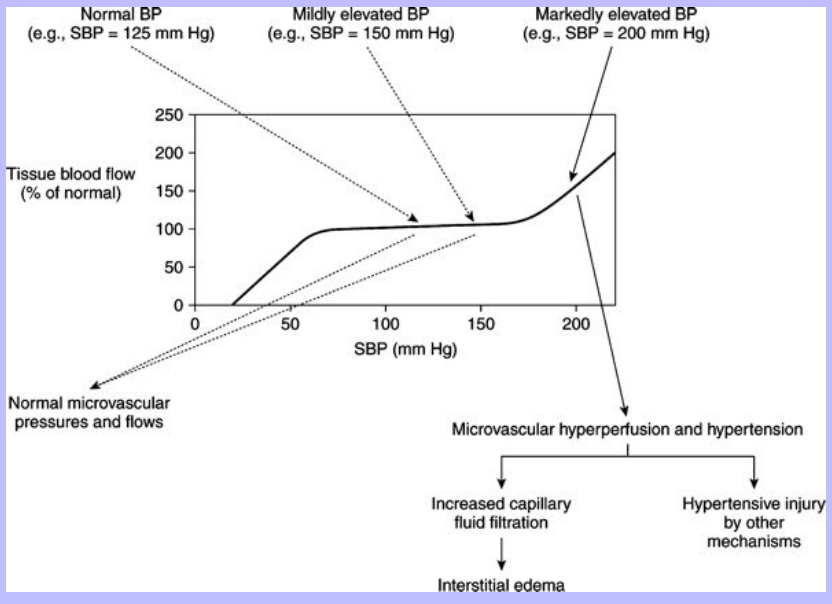
Perhaps because routine screening of animals for hypertension by BP measurement is uncommon, sudden onset of blindness from hypertensive retinopathy is one of the most common presenting complaints for animals with systemic hypertension. As with other microvascular beds (see Figure 129-2), once the upper limit of autoregulation has been reached, any subsequent rise in choroidal arteriolar and capillary flows and pressures leads to plasma leakage with associated abnormalities, including edema, hemorrhage, and detachment of the retina.

129.6 RENAL EFFECTS OF HYPERTENSION

Hypertension and kidney disease are integrally linked in human beings, with hypertension serving as a leading cause of renal failure and renal failure frequently contributing to the genesis and maintenance of systemic hypertension. This applies to any type of kidney disease, be it acute or chronic; vascular, tubulointerstitial, or glomerular; or mild, moderate, or severe. It has been argued that high BP and kidney disease are a complex cause-effect dilemma (i.e., a "chicken and egg" issue), but this is probably not the case in dogs and cats. There is no evidence that a persistent elevation of BP in the absence of a pre-existing primary renal disease can produce structural renal damage in dogs and cats. Indeed, there is evidence to the contrary. The more common scenario is the initial presence of a kidney disease, with activation of the renin-angiotensin system and/or interference with renal sodium handling, which produces systemic hypertension, which then is capable of damaging the diseased kidney.

474 475

Figure 129-2 The relationship between systolic blood pressure (SBP) and tissue blood flow demonstrates a range of pressures wherein tissue blood flow is maintained constant (autoregulated) by the local vasculature. When SBP exceeds this range, tissue hyperperfusion and hypertension, and subsequent injury, ensue (see text for details).



Systemic hypertension can contribute to renal injury in dogs with kidney disease, and the same is likely to be the case in cats. The renal microcirculation is unique in that the glomerular capillary bed is both preceded and followed by an arteriole. In kidney disease of any type, patchy areas of ischemia may result in overproduction of renin, with resultant increases in circulating and/or local concentrations of angiotensin II (Figure 129-3). Systemic generation of angiotensin II raises cardiac output and peripheral vascular resistance, exacerbating systemic hypertension. Critically, if kidney disease is present, the afferent arteriole is dilated. This site-specific dilatation represents an adaptive (perhaps maladaptive) response to the presence of a kidney disease. Constriction of the efferent arteriole by angiotensin II, coupled with this afferent dilatation, dramatically raises glomerular capillary pressure. The affected glomerular capillary bed and its associated nephron and interstitium are susceptible to hypertensive injury. Chronically sustained, hypertension in a dog or cat with kidney disease and a SBP greater than 160 mm Hg can lead to nephron destruction and can contribute to progressive renal failure.

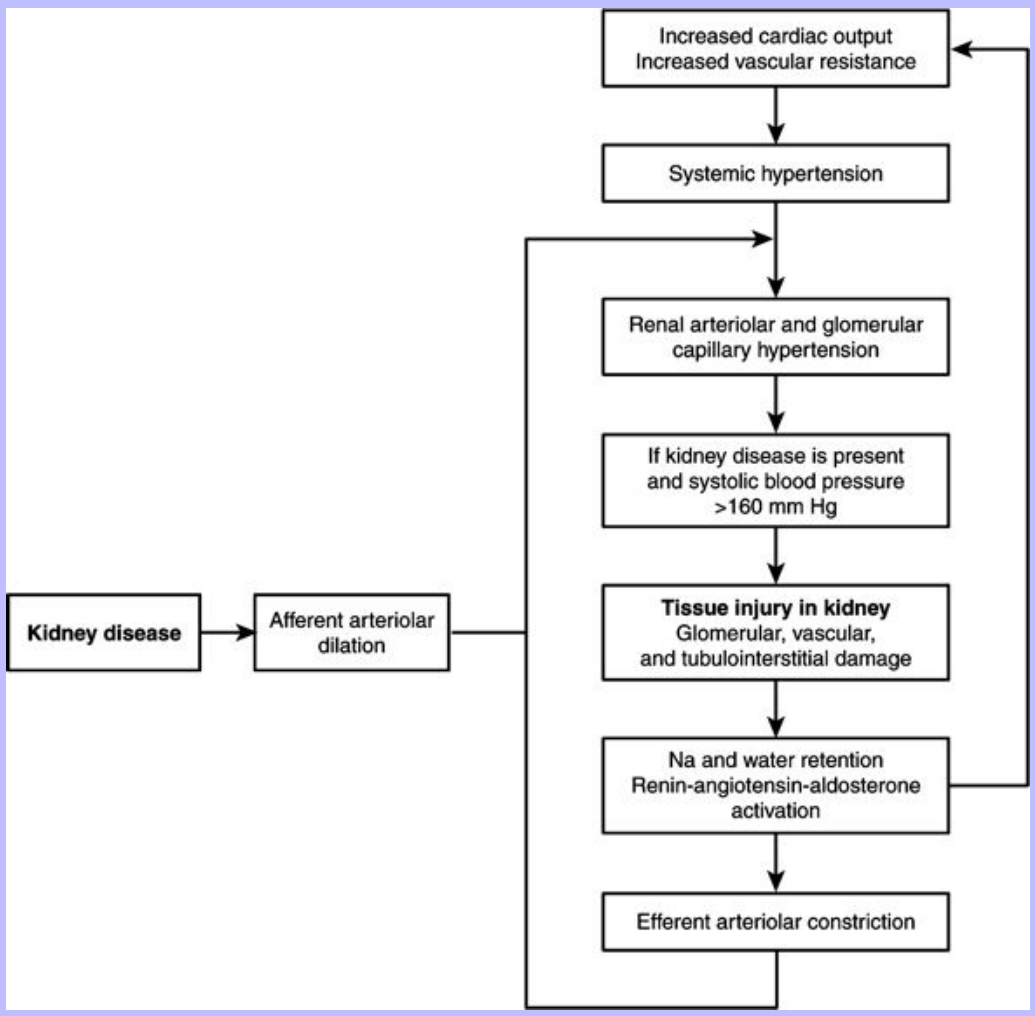
129.7 RENOPROTECTIVE ROLE OF ANTIHYPERTENSIVE AGENTS

Kidney function (i.e., GFR and microvascular pressures and flows) is generally preserved during variations in BP as a result of the intrinsic property of renal vasculature referred to as autoregulation (see Figure 129-2). The normal kidney autoregulates, or maintains stability of, its own blood flow and GFR and is capable of achieving this effect despite variations in mean BP from 60 to 160 mm Hg. Unfortunately, studies have shown that animals with acute and chronic renal insufficiency lose the ability to autoregulate renal blood flow and GFR, making them more susceptible to renal damage from increases in BP.

In animals with systemic hypertension and chronic kidney disease, the most frequently recommended antihypertensive agents are vasodilators because they tend to produce renal vasodilatation, preserving GFR. Two classes of vasodilatory agents have proved to have renoprotective effects in rodents and human beings; these are the angiotensin-converting enzyme inhibitors (ACEIs) and the calcium channel antagonists (CCAs). As noted above, glomerular capillary pressure, the largest driving force for GFR and a site for the initiation of the deleterious effects of hypertension in the kidney, depends on afferent and efferent arteriolar tone. Dilatation of the afferent arterioles or constriction of the efferent arterioles increases glomerular capillary pressure (undesirable) and GFR (desirable).

An antihypertensive with a vasodilating effect at the efferent arteriole, such as an ACEI (e.g., benazepril, enalapril, ramipril, or spirapril), lowers BP by producing systemic vasodilatation and may have other beneficial effects in hypertensive dogs with kidney disease. In cats, the role of the renin-angiotensin system in the maintenance of systemic hypertension has been questioned. However, these agents may prove efficacious, because they lower intraglomerular pressure, presumably through inhibition of intrarenal formation of angiotensin II. Alternative methods of interfering with the renin-angiotensin-aldosterone system have not been fully evaluated in veterinary medicine (e.g., aldosterone and angiotensin receptor antagonists).

Figure 129-3 Kidney disease and systemic hypertension are closely linked in a series of complex processes that are self-perpetuating (see text for details).



Some drugs classified as CCAs reduce total peripheral vascular resistance, leading to a decrease in BP. Amlodipine besylate is a long-acting dihydropyridine calcium antagonist that has been used effectively in hypertensive cats. The CCAs preferentially dilate the afferent arteriole. Vasodilatation at this site tends to raise intraglomerular pressure and could promote renal injury and/or proteinuria. However, these agents are most frequently used in cats, in which they are quite effective at lowering BP. The overall effect on intraglomerular pressure of reducing BP coupled with afferent arteriolar vasodilatation is hard to predict. Furthermore, the calcium channel antagonists have nonhemodynamic effects that may offer renoprotection. In dogs, in which CCAs seem less effective at lowering BP, use of these drugs as sole agents could predispose the animal to renal damage by allowing the high BP to be transmitted unimpeded through a dilated afferent arteriole to the susceptible glomerular capillary tuft.

Currently, co-administration of a CCA and an ACEI is advocated for hypertensive human beings with chronic kidney disease, because this therapy may reduce BP while equally dilating both the afferent and efferent arterioles, producing a balanced effect on the GFR and glomerular capillary pressure.

130 CHAPTER • 130 Management of Hypertension

Patti S. Snyder

Kirsten L. Cooke

Once a diagnosis of hypertension has been made, the decision to treat and the choice of antihypertensive medication depend on numerous factors, including the presumed cause of the hypertension, the presence of target organ damage, and the severity of the blood pressure elevation. The goals of antihypertensive therapy should be to reduce blood pressure and slow the progression of target organ damage caused by long-standing hypertension.

If an underlying cause of the hypertension can be identified, this condition should be addressed in the overall treatment plan for the hypertension. However, even if the presumed cause of the hypertension is controlled, antihypertensive treatment is usually continued indefinitely. If target organ damage is present, treatment of hypertension is usually initiated at systolic blood pressures greater than 160 mm Hg (Table 130-1). If target organ damage is not observed, documentation of a systolic blood pressure greater than 180 mm Hg on three separate occasions is considered sufficient evidence to begin treatment to lower blood pressure. There is less agreement among clinical researchers regarding treatment decisions based on diastolic blood pressure measurements.

Hypertensive animals that show neurologic signs are seen infrequently; however, if neurologic signs are observed, immediate intervention is necessary, using an antihypertensive agent that exerts gradual but effective blood pressure control. The more typical presentation is the pet with severe hypertension without life-threatening signs; these animals often exhibit such signs as blindness due to retinal hemorrhage or detachment. Because the stress of hospitalization could contribute further to elevations in blood pressure, most hypertensive animals are not hospitalized unless neurologic signs are seen. However, animals with severe hypertension deserve close monitoring, which may necessitate frequent visits for evaluation and blood pressure measurement until the hypertension improves.

Table • 130-1 Drugs Used to Treat Hypertension in Cats and Dogs

	DOSAGE	
DRUG	**CATS**	**DOGS**
Furosemide (Lasix, generic)	1–4 mg/kg PO, IV q12-48h	2–4 mg/kg PO, IV q8-24h
Atenolol (Tenormin, generic)	2 mg/kg PO q12-24h	0.25–1 mg/kg PO q12-24h
Propranolol (Inderal, generic)	2.5–5 mg total dose PO q8-12h	0.2–1.0 mg/kg PO q8-12h
Enalapril (Enacard, Vasotec, generic)	0.25–0.5 mg/kg PO q12-24h	0.5 mg/kg PO q12-24h
Benazepril (Lotensin, Fortekor)	0.25–0.5 mg/kg PO q24h	0.25–1.0 mg/kg PO q24h
Ramipril (Altace, Vasotop)	None Available	0.125–0.25 mg/kg q24h
Nitroprusside (Nitropress)	None Available	2–10 µg/kg/min IV CRI
Phenoxybenzamine (Dibenzyline)	0.25–0.5 mg/kg PO q12h	0.25–1.5 mg/kg PO q8-12h
Prazosin (Minipress, generic)	None	0.5–2 mg total dose PO q8-12h
Amlodipine (Norvasc, Istin)	0.18–0.3 mg/kg PO q24h	0.2–0.4 mg/kg PO q24h
Acepromazine (Promace, generic)	0.05–0.1 mg/kg SC, IV	0.05–0.1 mg/kg SC, IV
Hydralazine (Apresoline, generic)	2.5–5 mg total dose PO q12-24h	0.5–3 mg/kg PO q12h

130.1 DIET

Salt restriction has been the foundation of antihypertensive therapy in human beings. The goal of sodium restriction is to decrease total body sodium and extracellular fluid volume. Unfortunately, with the exception of a small population of dogs with essential hypertension, sodium restriction alone has not been shown to ameliorate hypertension in naturally hypertensive dogs and cats. Although one recent study showed that feeding a food with a moderately increased sodium level (1.0% sodium) to normotensive cats did not cause an elevation in systolic blood pressure, it should be noted that these were young cats with normal blood pressure. It is currently recommended that diets high in sodium (1.3% or higher) be discontinued if possible.

Although an obesity-induced hypertension dog model exists, and overweight dogs have slightly higher blood pressures than dogs with normal body weights, the feeding of calorie-restricted diets has not been shown to lower blood pressure in obese, spontaneously hypertensive dogs and cats.

130.2 DIURETICS

By contracting the extracellular fluid volume, diuretics decrease blood pressure. Although still commonly used in hypertensive humans, diuretics in general have not been of benefit in spontaneously hypertensive dogs or cats; however, some clinical researchers suggest that furosemide may be useful on an acute basis when used in conjunction with other antihypertensive agents. Diuretics should not be used in dehydrated, hypertensive patients or those with metabolic imbalances such as hypokalemia.

477 478

130.3 ADRENERGIC BLOCKING AGENTS

Beta-adrenergic receptor blockers are thought to decrease blood pressure by reducing the heart rate and cardiac contractility, thereby decreasing cardiac output (an important component of blood pressure). No difference is apparent in the antihypertensive effects of the cardioselective beta blocker atenolol and the nonselective beta blocker propranolol. The advantages of atenolol are that less frequent dosing is required, and fewer $beta_2$-blocking effects (e.g., bronchoconstriction) are seen. Propranolol, when used as a single antihypertensive agent, has not been effective in hypertensive cats. Even when it is combined with enalapril and phenoxybenzamine, few cats show substantial improvement in blood pressure. Recently, propranolol and atenolol have been used in conjunction with the calcium channel blocker amlodipine in cats with refractory hypertension.

Beta blockers are considered the treatment of choice in hypertensive, hyperthyroid cats, because excess thyroid hormone causes an exaggerated response to catecholamines. If the hypertension fails to respond to beta blocker therapy, amlodipine can also be used in hyperthyroid cats. There is limited experience with the antihypertensive effects of beta blockers in hypertensive dogs. Beta blockers should not be used as an antihypertensive agent in dogs suspected of having hypertension due to a pheochromocytoma.

Blocking of postsynaptic $alpha_1$-receptors in blood vessels results in vasodilatation. Phenoxybenzamine, an alpha-adrenergic blocking agent, has been used with mixed results alone and in combination with ACEIs or amlodipine in hypertensive cats. Phenoxybenzamine is considered the antihypertensive drug of choice in dogs with pheochromocytomas. Another alpha-adrenergic blocker, prazosin, has been reportedly used in hypertensive dogs.

Labetalol, a beta-and alpha-receptor blocker, has received attention in human medicine as an antihypertensive agent for which the primary antihypertensive effect is vasodilatation by alpha-receptor blockade. Because of its

fast onset of action, it may be useful in emergency settings; however, experience with the drug in veterinary medicine currently is limited.

130.4 ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

Angiotensin-converting enzyme inhibitors (ACEIs) control blood pressure by blocking the conversion of angiotensin I to angiotensin II, thereby reducing circulating angiotensin II, a potent vasoconstrictor. Reducing angiotensin II concentrations also decreases the secretion of antidiuretic hormone and aldosterone, which promote sodium secretion and therefore water excretion, effectively decreasing extracellular fluid volume and lowering blood pressure. Plasma renin activity and angiotensin I concentrations were not elevated but aldosterone concentrations were increased in hypertensive cats with chronic renal failure, compared with normotensive control cats. However, in a study of 16 hypertensive cats, plasma aldosterone did not change significantly with the administration of the ACEI benazepril or enalapril, and hypertension remained uncontrolled in 14 of 16 cats. In contrast, Brown and others showed that benazepril decreased both glomerular capillary pressure and systemic arterial blood pressure in an experimental feline model of chronic renal insufficiency.[1]

No one has compared the antihypertensive effects of the various ACEIs currently available in hypertensive dogs or cats, and most veterinary experience with ACEIs stems from their use in animals with congestive heart failure. The ACEI dosage used to treat hypertension appears to be similar to that used for congestive heart failure, although for hypertension some clinicians have used slightly higher doses if the animal did not have renal compromise and was not receiving concomitant diuretic therapy.

The number of dogs that require antihypertensive therapy is small compared to the number of cats that are hypertensive, and our experience in treating hypertensive dogs is considerably less, therefore minimal information is available on effective antihypertensive agents in dogs. Currently, the first-line therapy option for dogs with systemic hypertension is either an ACEI or a calcium channel blocker, usually amlodipine. When enalapril was given to dogs with idiopathic glomerulopathy, blood pressure decreased significantly (even in animals that were not hypertensive).

Even if control of hypertension is not optimal with an ACEI, the drug may have other beneficial actions, such as renoprotection. In refractory hypertension, ACEIs have been combined with other classes of antihypertensive agents, such as beta blockers and calcium channel blockers, to improve blood pressure control.

130.5 CALCIUM CHANNEL BLOCKERS

The calcium channel blockers decrease blood pressure by promoting vasodilatation and preventing an increase in the cytosolic calcium in vascular endothelial cells that is necessary for vasoconstriction.

Amlodipine besylate, a member of the dihydropyridine class of calcium channel blockers, is the treatment of choice in cats with systemic hypertension. Its long duration of action allows for once daily dosing, and it is safe to use in animals with renal compromise, a common finding in cats with hypertension.

Amlodipine is the only antihypertensive agent proven to be effective in a placebo-controlled clinical trial of naturally occurring systemic hypertension in cats. In this study, systolic blood pressure declined significantly after 1 week of therapy (pretreatment value, 212 mm Hg; post-treatment value, 160 mm Hg) and remained controlled when the cats were re-examined 4 months later.[2] Amlodipine was also effective in controlling hypertension in cats with surgically induced renal insufficiency and hypertension. Most recently, amlodipine was shown to lower systolic blood pressure from a mean of 202.5 mm Hg to 153 mm Hg in 20 hypertensive cats. In hypertensive cats

with secondary ventricular hypertrophy, amlodipine administration resulted in resolution of the hypertrophy in 50% of the cats. Although amlodipine has been used safely in cats with renal dysfunction, there have been scattered reports of worsening azotemia in a small percentage of cats given the drug. For this reason, re-evaluation of a serum biochemistry panel is advised 1 to 2 weeks after initiation of amlodipine therapy.

Although there is less reported experience with amlodipine in hypertensive dogs, it is often prescribed as a first-line therapy for hypertension. If the drug is not effective at controlling hypertension in dogs, an ACEI can be combined with or substituted for the amlodipine.

130.6 COMBINATION THERAPY

Several clinical investigators have used ACEIs with beta blockers, or amlodipine combined with either beta blockers or ACEIs, in attempts to control blood pressure in cats with particularly resistant hypertension. Unfortunately, because no clinical reports are available on large numbers of cats or dogs effectively treated with combination therapy, information is lacking regarding preferred combinations or efficacy.

478
479

130.7 OTHER THERAPIES

The phenothiazine derivative acepromazine maleate is a vasodilating agent commonly used in most veterinary practices. Its blood pressure–lowering effects are believed to be associated with alpha-adrenergic blocking effects. In the acute setting, when immediate blood pressure control is needed and other antihypertensive agents are not available, acepromazine can be administered. The vasodilator hydralazine has been used in cats receiving renal allograft that showed clinical signs of systemic hypertension. Administration of hydralazine reduced systolic blood pressure to the normal range within 15 minutes.

Sodium nitroprusside releases nitric oxide in vascular smooth muscle and causes vasodilatation (both arterial and venous). Its primary use has been in dogs with fulminant congestive heart failure. Nitroprusside should be administered as an intravenous constant-rate infusion, with an infusion pump used to improve the accuracy of dosing. However, it should be noted that because of vascular adaptations to long-standing, elevated blood pressure, abrupt decreases in blood pressure in chronically hypertensive animals can compromise cerebral perfusion and may not be in the patient's best interest.

130.8 ADDITIONAL TREATMENT RECOMMENDATIONS

Pet owners should be closely questioned about other drugs the hypertensive animal may be receiving that could affect blood pressure. The administration of corticosteroids, phenylpropanolamine, subcutaneous fluids, and even topical preparations such as ocular phenylephrine could make blood pressure control more difficult in some hypertensive patients. If possible, these drugs should be discontinued, or the lowest possible dose should be used.

Re-evaluation of the hypertensive patient should include appropriate biochemical evaluation (serum biochemistry panel, thyroid testing), funduscopic examination, and indirect blood pressure measurement. The frequency of the re-evaluations depends on the patient's clinical signs, the type and severity of end-organ damage, and the degree of blood pressure elevation. Re-examination may also be dictated by any potential underlying medical problems that could contribute to or cause the blood pressure elevation. Goals for successful control of hypertension are still being debated; however, a general guideline is a systolic blood pressure under 160 mm Hg in an awake, unstressed animal.

When hypertension is diagnosed, our initial response is a desire to lower blood pressure immediately to protect organs from further damage. In most of our patients, hypertension has been a long-standing condition when the diagnosis is made. Long-standing hypertension leads to adaptations in the cerebral vasculature such that a rapid drop in blood pressure may compromise cerebral perfusion. Rapid decreases in blood pressure are most often associated with administration of parenteral drug therapy, therefore these drugs should be reserved for cases in which the benefits of parenteral therapy outweigh the risk posed by the hypertension.

Because antihypertensive therapy is likely to be lifelong, administration of a single agent with a long duration of action (preferably an agent administered once daily) is ideal for improving owner compliance. If adverse effects are observed, another drug, usually from a different class, should be substituted. If the response to the initial agent is inadequate, the dose may be increased (if possible) or another agent, usually from another class, can be combined with the initial agent. If blood pressure control is still not achieved, monitoring of the blood pressure throughout the day to observe trends before and after drug administration may be useful. Owner and patient noncompliance and inadequate management of the underlying cause of the hypertension should also be considered if control of hypertension is difficult. A final consideration for inadequate control of hypertension is the concomitant use of other drugs that could contribute to the increased blood pressure.

130.8.1 Adverse Effects

Lowering of the blood pressure below normal is a potential complication of any antihypertensive agent and, as mentioned earlier, rapid lowering of blood pressure can lead to cerebral ischemia. These are less likely to occur with the commonly used oral antihypertensive therapies. Anorexia, vomiting, and diarrhea are the most common side effects seen with the antihypertensive agents, but the development of azotemia or worsening azotemia may also be seen once an antihypertensive agent is initiated. Monitoring of renal parameters on serial biochemistry panels is advised for any animal receiving chronic drug administration, including animals on long-term antihypertensive therapy.

131 CHAPTER • 131 Hypotension

Lori S. Waddell

H*ypotension* is defined as a systolic arterial blood pressure of less than 80 mm Hg and/or a mean pressure of less than 60 mm Hg in either dogs or cats. Causes of hypotension include decreased preload to the heart, decreased vascular tone, and cardiac dysfunction. Untreated hypotension can lead to *shock,* which is defined as inadequate tissue perfusion and oxygen delivery to the tissues. Treatment of hypotension should always be aimed at correcting the underlying problem. Recognition and treatment of hypotension are essential to prevent the development of refractory shock, organ failure, and death (Figure 131-1).

Blood pressure provides a measurement of tissue perfusion. The two are not equivalent, but blood pressure monitoring is the simplest means of obtaining an objective parameter. Subjective measures of tissue perfusion are obtained by physical examination; they include pulse quality, mucous membrane color, capillary refill time, and heart rate and rhythm. Combined with blood pressure monitoring, these parameters provide the basis for a more accurate assessment of tissue perfusion. A normal blood pressure does not necessarily mean that the tissues are adequately perfused, as blood pressure may be maintained with severe peripheral vasoconstriction.

131.1 CLINICAL MANIFESTATIONS

The clinical signs associated with hypotension depend on the severity and cause of the condition. In dogs, hypotension is usually associated with tachycardia, bounding to weak pulses, pale mucous membranes, slow capillary refill time, mental dullness, and weakness. If the underlying cause is sepsis, the mucous membranes may be injected or red with a rapid capillary refill time. Cardiac causes of hypotension can also change the clinical picture, with arrhythmias; weak, irregular pulses; and even severe bradycardia possible. Hypotensive cats also usually have tachycardia, poor pulse quality, pale mucous membranes, slow capillary refill time, mental dullness, and weakness. However, unlike dogs, cats with sepsis or systemic inflammatory response syndrome (SIRS) often have bradycardia rather than tachycardia and rarely have injected mucous membranes. In both species, hypotension is often associated with decreased urine output, hyperventilation, hypothermia, and cold extremities.

Inability to palpate pulses peripherally can be useful in assessing blood pressure. When metatarsal pulses are palpable, the systolic blood pressure is above 70 to 80 mm Hg. Although measurement of blood pressure can confirm the presence of hypotension, the diagnosis can certainly be made on physical examination findings alone.

131.2 PATHOGENESIS

Blood pressure is dependent on cardiac output and peripheral vascular resistance. Cardiac output is determined by heart rate, contractility, preload, and afterload. The three main causes of hypotension are decreased preload, decreased cardiac function, and decreased vascular tone (Box 131-1). These may occur individually or in combination.

Multiple compensatory mechanisms are activated by hypotension. The baroreceptors in the carotid sinuses and aortic body sense a lack of stretch, resulting in increased sympathetic nervous system activation, increased release of antidiuretic hormone (ADH) and adrenocorticotropic hormone (ACTH) from the pituitary, and increased release of catecholamines and cortisol from the adrenal glands. These changes result in an increased heart rate, increased vasoconstriction, and increased water retention by the kidneys. Simultaneously, the macula densa in the glomeruli are affected, and the renin-angiotensin-aldosterone system is activated, resulting in sodium retention by the

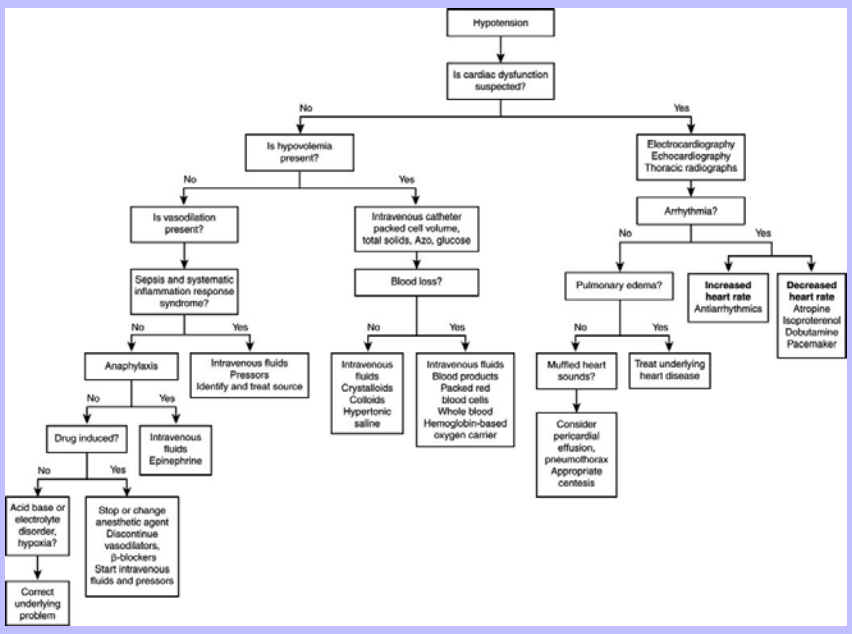
kidneys and further vasoconstriction. These mechanisms serve to increase blood volume by means of sodium and water retention and to preferentially perfuse the brain and heart while decreasing perfusion to the skin, muscles, and abdominal organs, including the kidneys. Recognition and treatment of hypotension are essential to prevent the development of refractory shock and organ failure. Acute renal failure is one of the most common consequences of hypotension, but others include decreased coronary artery perfusion due to the increased heart rate, increased risk of bacterial translocation from the gastrointestinal tract, impaired hepatic function, and activation of the coagulation cascade.

Hypovolemia results in decreased cardiac output secondary to decreased venous return to the heart, which results in decreased preload. Moderate to severe hypovolemia must be present to affect blood pressure due to the normal compensatory actions that occur, including increased heart rate to maintain cardiac output and increased peripheral vascular resistance secondary to vasoconstriction. The compensatory mechanisms maintain adequate blood pressure until more than 20% to 25% of the intravascular volume has been depleted. Hypovolemia can occur with blood loss or increased fluid losses secondary to vomiting, diarrhea, polyuria, or third spacing of fluid.

Restriction of filling of the heart also results in decreased preload, decreased cardiac output, and hypotension. Pericardial effusion with tamponade and restrictive pericarditis can result in hypotension by this mechanism. Severe pneumothorax and positive pressure ventilation can also reduce venous return to the heart. Hypertrophic cardiomyopathy in cats reduces left ventricular volume, thereby reducing preload and cardiac output.

Bradyarrhythmias can affect blood pressure by reducing cardiac output, especially when the heart rate is extremely slow. Although the pulses may be strong when the bradyarrhythmias occur, overall cardiac output can be drastically reduced by the infrequency of systole. The resulting low cardiac output may be severe enough to cause syncopal episodes secondary to hypotension and decreased perfusion of the brain. Tachyarrhythmias can result in hypotension by reducing preload to the heart. At very rapid heart rates, filling of the heart is limited by the relatively short time of diastole. This results in reduced cardiac output despite an increased heart rate. 480 482

Figure 131-1 Algorithm for differential diagnoses and treatment of hypotension.



131.2.1 Box • 131-1 Causes of Hypotension

131.2.1.1 Decreased Preload

Hypovolemia

Hemorrhage

Trauma

Gastrointestinal losses

Polyuria

Hypoadrenocorticism

Effusions or third spacing of fluid

Burns

Heatstroke

131.2.1.2 Decreased venous return

Pericardial tamponade

Restrictive pericarditis

Severe pneumothorax

Positive pressure ventilation

Gastric dilatation and volvulus

Heartworm disease (caval syndrome)

131.2.1.3 Decreased Cardiac Function

Cardiomyopathy

Valvular disease

Bradyarrhythmias

Tachyarrhythmias

Electrolyte abnormalities

Acid-base disturbances

Severe hypoxia

131.2.1.4 Decreased Vascular Tone

Sepsis/systemic inflammatory response syndrome (SIRS)

Anaphylaxis

Neurogenic

Drug induced (anesthetic agent, vasodilators [e.g., beta blockers, calcium channel blockers])

Electrolyte abnormalities

Acid-base disturbances

Severe hypoxia

Decreased cardiac output can also occur due to primary cardiac disorders. Dilated cardiomyopathy is characterized by reduced stroke volume and reduced cardiac output caused by decreased contractility. Valvular incompetence, resulting in regurgitant flow, also causes decreased stroke volume. Other causes of decreased cardiac contractility include myocarditis, myocardial infarction, myocardial depression secondary to sepsis, SIRS, anesthetic drugs, beta blockers and calcium channel blockers, and acid-base and electrolyte abnormalities.

Decreased peripheral systemic resistance can also cause hypotension. Common causes of vasodilatation are sepsis/SIRS; anaphylaxis; anesthesia; use of vasodilators, including beta blockers and calcium channel blockers; electrolyte abnormalities; and acid-base disturbances. Many of these mechanisms also affect cardiac contractility, resulting in hypotension mediated by decreased cardiac output and vasodilatation simultaneously.

131.3 MEASUREMENT OF BLOOD PRESSURE

Blood pressure monitoring can be divided into two main types, noninvasive and invasive methods. The noninvasive methods are most commonly used, and in dogs and cats usually consist of either an oscillometric system (Cardell Monitor, Sharn Veterinary, Tampa, Florida or Dinamap, Critikon, Tampa, Florida) or Doppler methods (Parks Electronics, Aloha, Oregon). Invasive blood pressure monitoring is performed by direct arterial pressure measurement and is the most accurate method available.

131.4 TREATMENT

It is essential that the treatment of hypotension always be aimed at correction of the underlying physiologic problem: decreased preload, cardiac dysfunction, or peripheral vasodilatation. Differentiation of cardiac and noncardiac causes of hypotension is a critical first step (Figure 131-1). If the animal is hypovolemic, intravenous fluids should be administered until euvolemia has been attained. If hypovolemia is severe enough to cause hypotension, a shock bolus should be given. The standard doses of isotonic crystalloids are 60 to 90 mL/kg/hour for dogs and 45 to 60 mL/kg/hour for cats. If colloids are indicated in place of crystalloids, approximately one fourth of the crystalloid dose should be given. Hypertonic saline is a rapid intravascular volume expander and can be used when immediate resuscitation is needed. The dose for hypertonic saline is 5 mL/kg given over 5 to 10 minutes for dogs and 3 to 4 mL/kg given over the same time period for cats. After administration of hypertonic

saline, it is essential to follow with one third to one half of a shock bolus of isotonic crystalloids to provide continued intravascular volume expansion and to replenish the interstitial space. If hypovolemia occurs secondary to blood loss, blood products, such as whole blood or packed red blood cells, or a hemoglobin-based oxygen-carrying solution should be administered to provide adequate oxygen-carrying capacity.

If the volume status is unknown or if there are concerns about overloading the animal with intravenous fluids, a central venous catheter can be placed for central venous pressure (CVP) monitoring. A low CVP (less than 0 cm H_2O) indicates hypovolemia due to fluid loss or vasodilatation secondary to decreased peripheral resistance. A high CVP (greater than 10 cm H_2O) indicates volume overload, right-sided heart failure, or increased pulmonary vascular resistance (afterload). If the significance of a CVP reading is questionable, a small test bolus of fluids can be given. A rapid bolus of 10 to 15 mL/kg of crystalloid or 3 to 5 mL/kg of colloid is used. The vascular bed is a compliant system, able to accommodate changes in volume with minimal changes in pressure. If the animal has a low CVP due to hypovolemia, the CVP will show either no change or a transient rise toward normal followed by a rapid decrease. The mean arterial pressure may also increase transiently. A bolus given to a dog or cat that is euvolemic usually causes a small increase in the CVP of 2 to 4 cm H_2O with a return to baseline within 15 minutes. A large increase (greater than 4 cm H_2O) and slow return to baseline (longer than 30 minutes) are seen with hypervolemia or reduced cardiac compliance.

If the animal remains hypotensive once euvolemia has been achieved, the use of pressors should be considered. Commonly used pressors include dopamine, epinephrine, and phenylephrine administered as constant-rate infusions. These drugs need to be titrated to effect, requiring frequent blood pressure monitoring. They should never be used in place of adequate volume expansion, because most dogs and cats with hypovolemia already have compensatory vasoconstriction.

482

483

Cardiac causes of hypotension must be addressed on a case by case basis. If tachyarrhythmias are the cause, antiarrhythmic therapy should be administered. Bradyarrhythmias may respond to medical therapy or may require placement of a pacemaker. Obstruction of cardiac filling by pericardial effusion or severe pneumothorax should be addressed by appropriate centesis. Positive inotropes should be administered when decreased cardiac contractility is suspected.

131.5 DIAGNOSTIC PLAN

Diagnosis of the underlying cause of the hypotension must often wait until after therapy has been initiated due to the critical nature of hypotension. History and physical examination abnormalities can often help in the determination of a tentative diagnosis, allowing therapy to be started. Initial diagnostics in an unstable hypotensive dog or cat should include packed cell volume, total solids, and glucose values and an estimate of the blood urea nitrogen level (Azostix, Bayer corporation, Elk-hart, IN). Electrolytes and acid-base status can also be helpful. Depending on the clinical signs, an electrocardiogram (ECG), abdominal and thoracic radiographs, abdominal ultrasonography, echocardiography, CVP and pulse oximetry determinations, and arterial blood gas analysis can be useful. A complete blood count, serum chemistry profile, and urinalysis should also be performed. If indicated, an ACTH stimulation test should be considered. If sepsis is suspected, blood and urine cultures should be done unless the source of sepsis can be directly cultured.

132 CHAPTER • 132 Clueing in Customers*

Leonard L. Berry

Neeli Bendapudi

Nobody likes going to the hospital. The experience is at best unnerving, often frightening, and, for most of us, a potent symbol of mortality. What's more, it's very hard for the average patient to judge the quality of the "product" based on direct evidence. You can't try it on, you can't return it if you don't like it, and you need an advanced degree to understand it—yet it's vitally important. Therefore when we're considering a doctor or a medical facility, most of us unconsciously turn detective, looking for evidence of competence, caring, and integrity—processing what we can see and understand to decipher what we cannot.

The Mayo Clinic doesn't leave the nature of that evidence to chance. By carefully managing a set of visual and experiential clues, Mayo tells a consistent and compelling story about its service to customers: At Mayo Clinic, the patient comes first. From the way it hires and trains employees, to the way it designs its facilities, to the way it approaches care, Mayo offers patients and their families concrete and convincing evidence of its strengths and values. The results are exceptionally positive word of mouth and abiding customer loyalty, which have allowed Mayo Clinic to build what is arguably the most powerful brand in health care—with very little advertising—in an industry where few institutions have any brand recognition beyond their local markets.

It's called "evidence management": an organized, explicit approach to presenting customers with coherent, honest evidence of your abilities. Evidence management is a lot like advertising, except that it turns a company into a living, breathing advertisement for itself. Other organizations manage evidence well, too. Ritz Carlton, for example, very effectively communicates outstanding personal service: Employees at all levels take note of customer preferences and are empowered to solve problems on the spot, continually tailoring the experience to each person. Mayo Clinic does not have all the answers; health care is a highly inventive industry, and many institutions could serve as fine examples to business. However, during our extensive study of the Mayo organization over a five-month period, we saw evidence— management practices that rival or surpass anything we've seen in the corporate sector, practices that are applicable outside of health care. As part of our research design, we interviewed approximately 1000 Mayo employees and patients, observed hundreds of doctor-patient visits at two of Mayo's three major campuses (Scottsdale, Arizona, and Rochester, Minnesota; the third is in Jacksonville, Florida), and stayed in the hospitals overnight as patients. In almost every experience and interaction, in subtle and not-so-subtle ways, we got the message that at Mayo Clinic, the patient comes first (Box 132-1).

Many businesses sell products that are intangible or technically complex—financial and legal services, software, and auto repair are just a few—and their customers naturally look for clues that can help explain what they don't understand or see. In fact, in just about any organization, the clues emitted by people and things (humanics and mechanics, respectively, as introduced to the management literature by Lewis Carbone and Stephan Haeckel) tell a story to customers or potential customers. The question for managers is whether the clues tell the intended story. Mayo Clinic's effectiveness at designing and managing evidence offers a lesson other service organizations would do well to heed: Understand the story you want to tell, and then make sure your people and your facilities provide evidence of that story to customers, day in and day out.

132.1 CLUES IN PEOPLE

When we interviewed Mayo patients, we were struck by how consistently they described their care as being organized around their needs rather than the doctors' schedules, the hospital's processes, or any other factor related to Mayo's internal operations. The actions of Mayo staff members, according to what we were told, clearly signal the patient-first focus. Here are representative remarks: “My doctor calls me at home to check on how I am doing. She wants to work with what is best for my schedule.” “When I had a colonoscopy, [my doctor] waited to tell me personally that I had a polyp because he remembered that my husband died from small bowel cancer, and he knew that I would be worried I may have the same thing.” “My oncologist is…the kindest man I have ever met. He related some of his personal life to me. I was more than my problem to him. He related to me as a person.”

Such glowing praise isn't limited just to the doctors and nurses. One patient, for example, was “amazed” at how well the people at the registration desk handle requests: “People who come up to the desk are nervous, or angry, or abusive. These ladies at the registration desk just keep their cool. I wish they could train the customer service reps in department stores.”

It's no accident that employees communicate a strong, consistent message to patients. Mayo explicitly and systematically hires people who genuinely embrace the organization's values. The clinic emphasizes the importance of those values through training and ongoing reinforcement in the workplace, a practice that began in the very early part of the twentieth century, when Drs. William and Charles Mayo started the organization. Indeed, William Mayo's credo—“The best interest of the patient is the only interest to be considered”—guides hiring decisions to this day.

It's difficult to get a job at Mayo Clinic because of intellect or technical skill alone. Demonstrated task competence is essential, of course, but the hiring managers are also trained in behavioral interview techniques, and they are expected to use them to elicit an applicant's values. A candidate may be asked, for instance, to discuss a time when he set a development goal for himself and how he met that goal or to describe the proudest moment in his career or even the moment he found most frustrating. Interviewers avoid discussing hypothetical situations that allow candidates to figure out the “right” answer and instead probe for specific details that reflect true experiences and perspectives. For example, a candidate who identifies making a difference in a patient's life as his or her proudest moment may be more attuned to Mayo's values than one who mentions achieving a career milestone.

486
487

132.1.1 Box • 132-1 The Research

Mayo Clinic has three major campuses (Rochester, MN; Scottsdale, AZ; and Jacksonville, FL); primary care clinics in more than 60 communities; 21 owned or managed hospitals; more than 2800 staff physicians; medical technology, medical publishing, laboratory, and health care benefits-administration businesses; and revenue in excess of $4 billion. It serves more than 500,000 individual patients annually.

For this article, we conducted the largest service study ever done at Mayo Clinic. During a 5-month period, we interviewed approximately 1000 Mayo patients, physicians, nurses, allied health staff, and managers at the original Rochester campus and the Scottsdale campus. We also collected data as participant observers, checking into the hospitals as patients, observing surgeries in the operating room and more than 250 doctor-patient interactions in the examination room, making hospital rounds, and flying on the Mayo One emergency rescue helicopter service. We formally studied service delivery in 14 medical specialties selected to provide a cross-section of the practice: cardiac surgery, cardiology, dermatology, emergency medicine, endocrinology, family medicine, gastroenterology, medical and

radiation oncology, neurology, orthopedic surgery, preventive medicine, thoracic surgery, transplant surgery, and urology. Mayo Clinic gave us complete access to study its service culture and processes, and the Mayo Clinic Institutional Review Board approved our study.

The people who make the cut—indeed, the people who are drawn to Mayo in the first place—are those who take pride in having the freedom to put patients first. We heard many doctors and nurses say that they appreciate being allowed to practice medicine as they feel it should be practiced. Those feelings of pride and the alignment of employees' attitudes with Mayo's values contribute to lower staff turnover across the board. Annual turnover among hospital nurses is only 4% at Mayo versus 20% for the industry as a whole—continuity that, in turn, helps boost the quality of care.

Once hired, all new employees go through an orientation process specifically designed to reinforce the patient-first mentality. The program for nonphysician employees—whether janitors, accountants, or nurses—is designed to help all staff people understand how their jobs affect patients' care and well-being. If housekeeping fails to maintain sanitary conditions, for instance, a patient's health may be compromised no matter how excellent the medical care received. Storytelling figures heavily in these programs, with the emphasis on how employees have used Mayo values to make difficult decisions on patients' behalf.

Storytelling continues in the workplace because, once people are away from the classroom, the idea of putting the patient first can seem distant and sometimes even unrealistic, given the stress and unpredictability of day-to-day work. Consider, for instance, one story featured at several orientation sessions and widely disseminated throughout the organization. A critically ill patient was admitted to the Scottsdale hospital shortly before her daughter was to be married, and she was unlikely to live to see the wedding. The bride told the hospital chaplain how much she wanted her mother to participate in the ceremony, and he conveyed this to the critical care manager. Within hours, the hospital atrium was transformed for the wedding service, complete with flowers, balloons, and confetti. Staff members provided a cake, and nurses arranged the patient's hair and makeup, dressed her, and wheeled her bed to the atrium. A volunteer played the piano and the chaplain performed the service. On every floor, hospital staff and visiting family and friends ringed the atrium balconies, “like angels from above,” to quote the bride. The wedding scene provided not only evidence of caring to the patient and her family but also a strong reminder to the staff that the patient's needs come first. They got the message: We heard the story multiple times in our interviews with employees.

Another story was initially told at a leadership development program for rising Mayo administrators. In one session, Mayo staff members shared experiences that showed how the service philosophy affects care. An emergency room physician told of a patient who walked into the ER with severe shortness of breath. When told she had a bacterial infection requiring immediate surgery, the woman expressed concern about her sick dog, which was in her illegally parked truck. The attending nurse assured her that he would move the truck and take care of the dog, but when he walked outside, what he saw was not a pickup but a semi, which he wasn't licensed to drive. He was about to have it towed—for $700—when he stopped to consider ways he might save the patient the expense. In the end, the nurse took it upon himself to obtain permission to park the truck at a nearby shopping center for a few days and find a fellow nurse—a former trucker—to drive the truck there. He took the dog to a veterinarian and then cared for it in his own home while the patient recovered. When asked what prompted him to do this, the nurse replied, “At Mayo Clinic, the patient's needs come first.”

Various events celebrating exceptional service on behalf of patients further reinforce employees' commitments. The Rochester campus hosts an annual Heritage Week, celebrating the clinic's history and values and reinforcing their relevance to Mayo's work today through historical presentations and displays, lectures, ecumenical and liturgical services, concerts, and social events. Employees, retirees, volunteers, patients, visitors, and members of the community are invited. Mayo Rochester also recognizes exceptional service with its quarterly campus-wide

Karis Award (Karis is Greek for caring). All staff members are eligible and can be nominated by a coworker, patient, or family member; the identity of the nominator is not disclosed, which removes political considerations from the process. One 1999 winner, a world-renowned colorectal surgeon with numerous scientific recognitions, told his tablemates at the award luncheon that he cherished the Karis more than any other award he's received, calling it, “The only award I have for just being a really good doctor.”

* Used by permission from *Harvard Business Review*, Feb 2003.

132.2 CLUES IN COLLABORATION

In 1910, William Mayo said, “In order that the sick may have the benefit of advancing knowledge, union of forces is necessary… It has become necessary to develop medicine as a cooperative science.” Dr. Mayo's vision profoundly influences the organization's approach to care. Patients experience the Mayo Clinic as a team of experts who are focused on patients' needs above all else. They perceive an integrated, coordinated response to their medical conditions and, often, to related psychological, social, spiritual, and financial needs. Elsewhere, doctors may be reluctant to admit to any gaps in their knowledge. Not so at Mayo. Mayo Clinic assembles the expertise and resources needed to solve the patient's problem. If a Mayo doctor can't answer a question and needs to bring someone else onto a team, she freely admits it to the patient. The doctors meet with one another and with the patient— visible evidence that they are collaborating to solve the patient's problem rather than passing it from one doctor to another. One patient we interviewed expressed a common sentiment when he said, “I have a lot of problems, and I like that I can go to Mayo and be seen by a team of specialists who work together to see the big picture.” Collaboration is particularly important because the institution's reputation has become so well known that patients often come in looking for a miracle. Many have consulted several other doctors and consider Mayo the last resort, so the physicians there regularly see patients with complex problems and high expectations, a situation that puts the doctors under extra pressure to make the right diagnoses and treatment decisions and not miss often subtle medical distinctions.

487

488

Mayo Clinic encourages this type of collaboration through various organizational incentives. All physicians are salaried, so they don't lose income by referring patients to colleagues, and the organization explicitly shuns the star system, downplaying individual accomplishments in favor of organizational achievements. In the words of one cardiovascular surgeon, “By not having our economics tied to our cases, we are free to do what comes naturally… to help one another.” Doctors who are focused on maximizing their incomes or who want to be the star of the show don't work for Mayo Clinic. A surgeon specializing in the liver explained, “The kind of people who are attracted to work for Mayo Clinic have a value system that places the care of those in need over personal issues such as salary, prestige, and power. There is little room for turf battles. It is never a problem to add [a new case] on to the workload of the day. It's simply the best thing to do for the patient.”

Mayo also supports teamwork with its use of technology. Staff members partner via a combination of face-to-face and remote collaboration using a sophisticated internal paging, telephone, and videoconferencing system that connects people quickly and easily. Remote teamwork through voice or virtual interaction is just as common as in-person teamwork at hallway or bedside consults. One physician told us, “I never feel I am in a room by myself, even when I am.” Recently, for example, a Mayo ENT specialist in Scottsdale called together 20 doctors from all three campuses to discuss a difficult case—a patient with skin cancer at risk for metastasis and, owing to the necessary surgery, nerve injury and disfigurement. The team, assembled in a day, met by videoconference for an hour and a half and reached a consensus for a course of treatment, including specific recommendations on how aggressively to sample the patient's lymph nodes and how best to reconstruct the surgical wound.

Mayo's electronic medical record (EMR) improves the clinic's ability to present a seamless, collaborative organization and manage the evidence that patients see. The EMR provides an up-to-date narrative of the patient's

symptoms, diagnoses, test results, treatment plans, procedures, and other related data, connecting in-and outpatient information and communicating across disciplines in outpatient practices. This connection is critical to patient-first decisions in ways that patients don't necessarily see. One emergency room physician said it had prevented her from intubating a patient who had asked not to be resuscitated, for instance, and others told of the importance of the EMR in managing patient medications to avoid allergic reactions or dangerous drug interactions. However, patients also notice and appreciate the single source of information, as we heard repeatedly in our research. One patient told us, “On my last visit, the doctor pulled up all my test scores from the past five years on a computer and showed me the trends, and we discussed what to do. I thought that was excellent.” In short, patients told us in numerous interviews that Mayo's team service gave them a sense that the organization was coordinating its resources to provide the best possible care, with the patients' needs foremost in employees' minds.

132.3 CLUES IN TANGIBLES

In health care, the visual clues about an institution's core values and the quality of care are particularly difficult to separate from the actual service because people spend significant time in the facility—some stay for days or even weeks. The physical environment is also connected to medical outcomes: The potential of design to promote healing through stress reduction has been documented in dozens of studies. For these reasons, more medical institutions are making an effort to create open, welcoming spaces with soft, natural light. Mayo Clinic goes further with its design philosophy, which is perhaps as well honed and articulated as that of any major service provider in America, and pays strict attention to how every detail affects the patient's experience.

From public spaces to exam rooms to laboratories, Mayo facilities have been designed explicitly to relieve stress, offer a place of refuge, create positive distractions, convey caring and respect, symbolize competence, minimize the impression of crowding, facilitate way finding, and accommodate families. In the words of the architect who designed Mayo Rochester's new 20-story Gonda Building, “I would like the patients to feel a little better before they see their doctors.” A well-designed physical environment has a positive impact on employees as well, reducing physical and emotional stress—which is of value not only to employees but also to patients because visible employee stress sends negative signals. In our interviews, patients commented on the lack of apparent stress; one said, “It did not seem like a doctor's office when we went to Mayo. There was no tension.”

The Gonda Building has spectacular wide-open spaces, a marble stairwell and floor, glasswork sculpture suspended above, and a multistory wall of windows looking onto a garden. The building's soaring lobby houses a cancer education center because, as one administrator put it, “The more visible the center, the more you remove the stigma of having cancer.” The lobby of Mayo Clinic Hospital in Scottsdale is also visually stunning, with its atrium, indoor waterfall, stonework, and wall of windows overlooking a mountain range.

Mayo doesn't limit its facilities' clue management to public spaces. After all, the scary stuff in a medical facility happens elsewhere—in the catheterization lab, in diagnostic imaging, in the hospital room. At Mayo hospitals, staff members write the names of attending doctors and nurses on a white board in every patient's room, which helps stressed-out patients and families keep track of multiple caregivers and serves as a visible clue that there's a real person they can talk with about any concerns. In-hospital showers, microwave ovens, and chairs that convert to beds are available for family members because, as one staff member explained, “People don't come to the hospital alone.” The pediatric section of Mayo's St. Mary's Hospital in Rochester transformed artwork by local schoolchildren into a colorful array of wall and ceiling tiles. The resuscitation equipment in pediatric examination rooms is hidden behind a large picture (which slides out of the way when the equipment is needed). While the hospital was under construction at the Scottsdale campus, officials arranged to have an automobile lifted into the building so physical rehabilitation patients would be able to practice getting in and out of a car in the privacy of a hospital.

Environmental clues in the outpatient setting are orchestrated just as carefully. Mayo Clinic buildings include quiet, darkened private areas where patients can rest between appointments. Public spaces are purposely made softer with natural light, color, artwork, piano music, and the sights and sounds of fountains. In examination rooms, the physician's desk is adjacent to a sofa large enough for the patient and family members, a design that removes the desk as a barrier between doctors and their patients.

Mayo also understands that the way employees present themselves sends a signal to patients. Patients don't encounter doctors in casual attire or white coats. Instead, the more than 2800 staff physicians wear business attire, unless they are in surgical scrubs, to convey professionalism and expertise. It's a dress code that some outside Mayo have called “pretentious”; yet we'd argue that it's no more pretentious than, say, the dress code for airline pilots. Airline passengers don't want to see their pilot in a polo shirt, and patients feel the same way about doctors. In effect, Mayo Clinic doctors—just like service workers in many other industries—work in a uniform; it is a visible clue that communicates respect to patients and their families.

Such attention to visual clues extends to the minutest detail. Mayo Rochester employee Mary Ann Morris, the administrator of General Service and the Office of Patient Affairs, often tells a story about her early days with the organization. She was working in a laboratory—a job that required her to wear a white uniform and white shoes—and after a hectic morning getting her two small children to school, she arrived at work to find her supervisor staring at her shoes. The supervisor had noticed that the laces were dirty where they threaded through the eyelets of Morris's shoes and asked Morris to clean them. Offended, Morris said that she worked in a laboratory, not with patients, so why should it matter? Her boss replied that Morris had contact with patients in ways she didn't realize—going out on the street wearing her Mayo name tag, for instance, or passing patients and their families as she walked through the halls—and that she couldn't represent Mayo Clinic with dirty shoelaces. “Though I was initially offended, I realized over time [that] everything I do, down to my shoelaces, represents my commitment to our patients and visitors,” Morris told us. “Twenty-eight years later, I still use the dirty shoelace story to set the standard for the service level I aspire to for myself and my coworkers.”

A dirty shoelace might seem minor, given the important work of caring for the ill; but a shoelace is something a customer can see, whereas medical expertise and technical ability are not. It's a piece of evidence—a small but integral part of the story Mayo tells to its customers. We aren't arguing that “patients first” is the only story a medical institution might choose to tell patients. A hospital might instead choose to signal, “We hire the smartest doctors,” and manage the evidence with prominent displays of academic credentials and awards, a lecture series, and heavy publicity about new research. What Mayo Clinic has done better than just about any organization we can think of, however, is clearly identify a simple, consistent message and then manage the evidence—the buildings, the approach to care, and yes, even the shoelaces—to support that message, day in and day out.

133 CHAPTER • 133 Rational Use of Diagnostic Tests

Andrew S. Peregrine

Diagnostic tests are used routinely in veterinary practice for screening animals and for identification of a specific target disorder in a diseased animal. However, very few diagnostic tests are accurate all the time. Thus not all animals that test positive necessarily have the target disorder under investigation. To correctly interpret diagnostic data, information is required on (1) a diagnostic test's *sensitivity*, the proportion of animals with the target disorder that test positive; (2) the test's *specificity,* the proportion of animals without the target disorder that test negative; and (3) the prevalence of the target disorder in animals similar to the one you are testing, or the probability that the animal has the target disorder before the test is run. Without this information, interpretation of diagnostic data is not possible.

Because diagnostic tests for heartworm *(Dirofilaria immitis)* infection in dogs are used commonly by veterinary practitioners, the following text describes how sensitivity, specificity, and prevalence estimates should be used to interpret data generated by these tests. The principles described apply to all diagnostic tests, including the clinical history and physical examination.

Heartworm antigen tests are the most common type of diagnostic method used to examine dogs for heartworm infection and typically have a sensitivity and specificity of approximately 80% and 98%, respectively.[1,2] Table 133-1 summarizes data from 1000 dogs when examined with such a test. Since the prevalence of heartworm infection in this population of animals is 30%, the total number of dogs infected with heartworm is 300. Because the antigen test's sensitivity is 80%, 240 (0.80 × 300) of the 300 infected dogs will test positive (cell *a*). The remaining 60 (300–240) infected dogs will test negative (cell *c*). Animals in cell *a* are therefore *true-positives,* whereas those in cell *c* are *false-negatives*. In light of the test's specificity of 98%, 686 (0.98 × 700) of the 700 uninfected dogs will test negative (cell *d*). The remaining 14 dogs (700-686) will erroneously test positive (cell *b*). Dogs in cell *d* are therefore *true-negatives,* whereas those in cell *b* are *false-positives*. In summary, the test has classified correctly dogs in cells *a* and *d* (*true-positives* and *true-negatives*) but has classified incorrectly dogs in cells *b* and *c* (*false-positives* and *false-negatives*).[3,4]

A sensitivity of 100% for the heartworm antigen test would rule out heartworm infection in all dogs that test negative. Likewise, if the test had a specificity of 100% all dogs that test positive could be diagnosed with heartworm.[3] However, because both parameters are less than 100%, some animals will be misclassified. *Predictive values* therefore need to be calculated. These indicate the likelihood that a test result has correctly classified the heartworm status of an animal. The *positive-predictive value* indicates the proportion of all animals that test positive for heartworm (cells *a* + *b*) that are truly infected with heartworm (cell *a*) and in Table 133-1 is 94.5%. Thus when one of the described dogs tests positive for heartworm antigen, the likelihood that the animal is truly infected with heartworm is 94.5%. Similarly, the *negative-predictive value* indicates the proportion of all animals that test negative for heartworm antigen (cells *c* + *d*) that are truly not infected with heartworm (cell *d*). In Table 133-1 this value is 92.0%. In other words, if a negative test result is obtained, it is 92% certain that the dog is not infected with heartworm.

Table • 133-1 Performance of a Heartworm Antigen Test* When Applied to a Dog Population with a Prevalence of Heartworm Infection of 30%

		Heartworm infection			
		Present	**Absent**	**Total**	
Heartworm antigen test	Positive	*a* 240	*b* 14	*a+b* 254	Positive-predictive value $=\frac{a}{a+b}=\frac{240}{254}=94.5\%$
	Negative	*c* 60	*d* 686	*c+d* 746	Negative-predictive value $=\frac{d}{c+d}=\frac{686}{746}=92.0\%$
	Total	*a +c* 300	*b +d* 700	*a+b+c+d* 1000	
		Sensitivity $=\frac{a}{a+c}$ $=\frac{240}{300}=80\%$	Specificity $=\frac{d}{b+d}$ $=\frac{686}{700}=98\%$		Prevalence $=\frac{a+c}{a+b+c+d}=\frac{300}{1000}=30\%$

* Sensitivity = 80%, specificity = 98%.

Unlike sensitivity and specificity, *predictive values* are strongly influenced by the true prevalence of the target disorder and therefore are not stable characteristics for a test.[4,5] To illustrate this point, Table 133-2 describes the performance of the aforementioned heartworm antigen test when applied to a population of dogs with a prevalence of heartworm infection of 0.5%. Although the sensitivity and specificity of the test are unaltered, the *positive-predictive value* has dropped to 16.7%. Thus only one in approximately every five positive test results is a *true-positive*. Therefore in this situation, heartworm infection should not be diagnosed solely on the basis of one positive antigen test (unlike the situation in Table 133-1). Additional diagnostic information is required to determine whether the positive result is a *true-* or *false-positive*. In contrast to the *positive-predictive value*, the antigen test's *negative-predictive value* of 99.9% (see Table 133-2) is higher than the situation described in Table 133-1. A negative antigen test result can therefore be used to rule out heartworm infection with a high level of certainty when applied to dogs with a prevalence of heartworm infection of 0.5%.

An understanding of the impact of prevalence on predictive values is of fundamental importance in interpretation of diagnostic data. Table 133-3 indicates how the *positive-* and *negative-predictive values* for the heartworm antigen test alter as the prevalence of heartworm infection increases from 0.02% to 50%. The sensitivity and specificity remain unaltered. Over this range the *positive-predictive value* increases from 0.8% to 97.6%, whereas the *negative-predictive value* decreases from 100% to 83.1%. Thus as the prevalence increases, the *positive-predictive value* increases. By contrast, the *negative-predictive value* decreases.[3] At a prevalence of infection of 10% or less the *positive-predictive value* is less than 90%. An additional diagnostic test(s) should therefore be used to confirm or refute a positive test result when obtained from such populations of dogs. Finally, in light of the effect of prevalence on predictive values (particularly *positive-predictive values*)[3,5], it is important to appreciate that the prevalence of heartworm infection is dependent on both the geographic location of an animal and on whether or not an animal has been on heartworm-preventive medication. Thus in every veterinary practice, routine screening of healthy dogs with heartworm antigen tests is actually carried out on two distinct populations of animals: those that were not on preventive medication the previous year and those that were. Although the prevalence of heartworm infection in the former dogs may be as high as 45%, the prevalence in the latter is typically less than 1%, even in high-prevalence

490

491

areas. Interpretation of an antigen test result is therefore dependent on which dog population is being examined. Both estimates can be obtained from dogs examined at a practice over the previous 1 to 2 years.

Table • 133-2 Performance of the Heartworm Antigen Test* Described in Table 133-1 When Applied to a Dog Population With a Prevalence of Heartworm Infection of 0.5%

		Heartworm infection			
		Present	Absent	Total	
Heartworm antigen test	Positive	*a*	*b*	*a+b*	Positive — predictive value
		4	20	24	$=\frac{4}{24}=16.7\%$
	Negative	*c*	*d*	*c+d*	Negative- predictive value
		1	975	976	$=\frac{975}{976}=99.9\%$
	Total	*a+c*	*b +d*	*a+b+c+d*	Prevalence
		5	995	1000	$=\frac{5}{1000}=0.5\%$

* Sensitivity =80%, specificity =98%.

Table • 133-3 Predictive Values for a Typical Heartworm Antigen Test* When Applied to Dog Populations With Various Prevalences of Heartworm Infection

REVALENCE OF INFECTION††	POSITIVE-PREDICTIVE VALUE‡‡	NEGATIVE-PREDICTIVE VALUE	1-(NEGATIVE-PREDICTIVE VALUE)§§
0.02%	0.8%	100%	0%
0.2%	7.4%	100%	0%
0.5%	16.7%	99.9%	0.1%
1.0%	28.8%	99.8%	0.2%
2.0%	44.9%	99.6%	0.4%
5.0%	67.8%	98.9%	1.1%
10.0%	81.6%	97.8%	2.2%
30.0%	94.5%	92.0%	8.0%
50.0%	97.6%	83.1%	16.9%

* Sensitivity =80%, specificity =98%.

† Pre-test probability of infection.

‡ Probability of infection following a positive test.

§ Probability of infection following a negative test.

491

492

If a diagnostic test is to be useful, it must have the potential to have a major effect on diagnosis, prognosis, or therapeutic decisions.[6] Thus, if the probability that an animal has a target disorder after application of a test is not significantly different from the probability prior to using the test (*the pre-test probability*), the diagnostic method does not have clinical utility. The *pre-test probability of the target disorder* is the proportion of animals with the

target disorder among all animals tested and is the same as the true prevalence. In the case of the heartworm scenario described at a prevalence of 30% (see Tables 133-1 and 133-3) the *pre-test probability* of heartworm infection is 30%. Since the *probability of infection following a positive test* is indicated by the *positive-predictive value*, the probability of infection at this prevalence for a test-positive animal is 94.5%. The positive result has therefore increased the certainty of infection by 64.5%. To what extent does a negative test rule out heartworm infection? The *probability of infection following a negative test* indicates the proportion of animals testing negative that are infected with heartworm and is calculated as 1-(*negative-predictive value*). At a prevalence of heartworm infection of 30% a negative antigen test decreases the probability of infection to 8% (see Table 133-3). Thus when the *pre-test probability of infection* is 30%, both positive and negative tests provide useful diagnostic information. In contrast, when the *pre-test probability of heartworm infection* is 0.5%, the probability of infection following a positive antigen test is 16.7%, whereas the probability of infection following a negative test is 0.1% (see Table 133-3). A positive test has therefore increased the probability of infection by 16.2% (from 0.5% to 16.7%), whereas a negative test has decreased the probability of infection by 0.4% (from 0.5% to 0.1%). Very little information has therefore been learned from both positive and negative test results in this situation.[3]

134 CHAPTER • 134 Principles of Drug Therapy

Dawn M. Boothe

134.1 DOSE-RESPONSE RELATIONSHIP

The intent of drug therapy is to induce a desired pharmacologic response for a sufficiently long period of time and avoid adverse drug events. Adverse events fall into two categories. Type A ("augmented"; Type I) generally are dose or duration dependent and result from plasma drug concentrations (PDC) that either are below (therapeutic failure) or exceed the maximum therapeutic range. As such, Type A events are largely predictable and potentially unavoidable if the clinician is sufficiently familiar with the drug and the patient.

134.2 DETERMINANTS OF DRUG DISPOSITION

134.2.1 Drug Movement

After administration of a fixed dose of a drug, several dynamic drug movements, largely dependent on passive diffusion, act in concert to determine PDC across time (Figure 134-1). The major movements include absorption from the site of administration to systemic circulation, defined as the major vessels and well-perfused organs; distribution of the drug from systemic circulation to tissues (target and non-target) and back again; and elimination of the drug from the body, accomplished by metabolism and excretion.

134.2.1.1 Plasma Drug Concentration Versus Time Curve: Clinical Pharmacokinetics

Pharmacokinetics scientifically (mathematically) describe the relationship of drug concentrations in a tissue across time such that dosing regimens and drug response can be predicted in animals. Because tissue samples cannot be collected easily, drug is most often measured in plasma. The four dynamic drug movements that affect PDC time most commonly follow first order, that is, a constant fraction rather than a constant amount of drug moves per unit time. As such, log drug concentrations are plotted across time (Figure 134-2, *A* and *B*). When the data is fit to the best line (based on sum of residuals), an equation is generated that allows prediction of drug behavior in a patient (or sample population). If the data can be accurately described by a single slope (as can occur only with intravenous [IV] administration [see Figure 134-2, *A*]), one drug movement (irreversible elimination) causes the change in PDC and the drug is described as following a one compartment (i.e., one component) open (i.e., the drug leaves the system) model. The slope of the PDC versus time curve describes the rate of elimination (k_{el}) of the drug and determines the time for 50% of the drug to be irreversibly eliminated from the body or the *elimination half-life*. The amount of tissue to which a drug is distributed is estimated by the volume of distribution (V_d), a theoretical and mathematically derived parameter that directly and inversely influences PDC after administration of a specific dose (see Figure 134-2). Calculation of V_d considers that concentrations of the drug occur throughout the body at the same concentration as that measured in the plasma. Clearance (volume/time) describes the fraction of the V_d from which drug is irreversibly eliminated and is calculated from V_d and k_{el}:

$$Cl = V_d \times k_{el}$$

Few drugs behave as a one compartment open model. If multiple drug movements influence the PDC (as occurs with any drug undergoing absorption from the site of administration; see Figure 134-2, *B*), two or more slopes may be necessary to describe the data, with each slope being influenced by one or more drug movements. Generally, computer-assisted linear regression "strips" each slope from the curve before the data is best fit to the multiple components. For multicompartment open models, each component is described by a slope or rate (ki) and y intercept PDC (e.g., A, B) (see Figure 134-2, Plot B). The first component of the curve is generally considered to represent drug distribution (slope = α) and the terminal (in this case, second) component elimination (e.g., k_{el}, or β, γ, depending on the number of components that describe the curve). The distribution *half-life,* calculated from α, is the time necessary for 50% of drug to be distributed. The elimination half-life is determined from the terminal component of the curve. Two V_d can be calculated, which represent either the central or peripheral compartments, respectively (see Figure 134-2, Plot B). Oral administration results in at least a two component model, with input generally also following first order input (see Figure 134-2, Plot C). The *absorption half-life* derived from the slope of the upswing of the oral PDC curve (K_a) is the time necessary for 50% of a drug to be absorbed.

493

493

494

Figure 134-1 The determinants of plasma drug concentration act in concert following administration of a fixed dosing regimen. Each determinant can be influenced by patient (e.g., species, age, gender), pharmacologic (i.e., drug interactions), or disease factors.

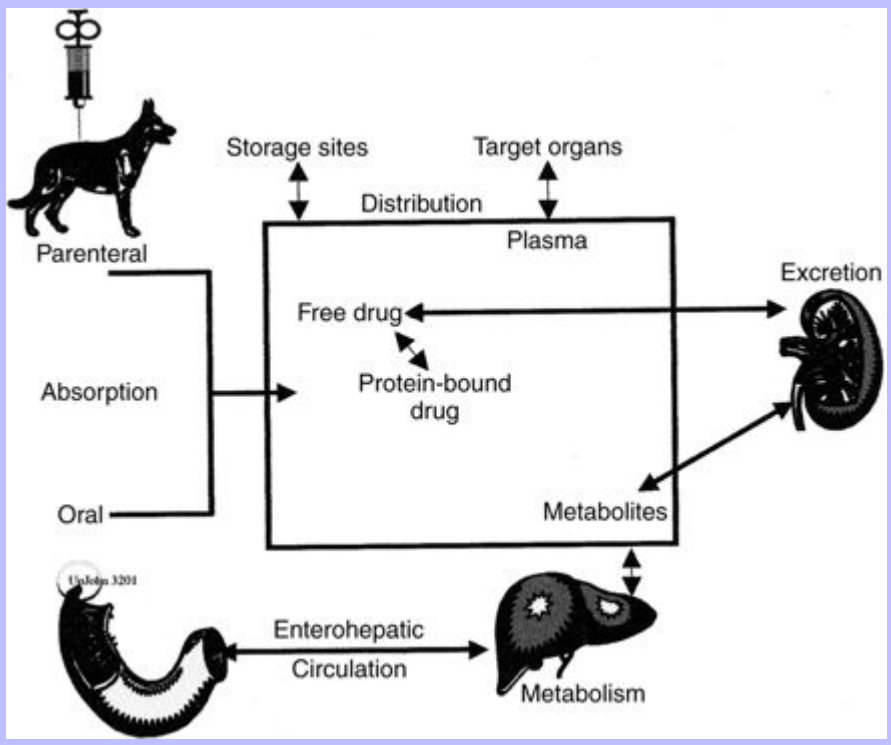

Figure 134-2 Log plasma drug concentration (PDC) versus time curves is subjected to linear regression. Following intravenous (IV) administration, a drug that fits a one-compartment open model will plot as a straight line. The equation y = mx + b when plotted semilogarithmically becomes $C = C_o e^{-kt}$ where *C* is the predicted drug concentration (mass/volume) at any time, *t*, following drug administration, C_o is the concentration of drug at time *0*, which is extrapolated back from the first data point, and *k* is the elimination rate constant ($time^{-1}$). The rate also can be calculated from two data points (i.e., peak and trough samples collected as part of therapeutic drug monitoring (*inset*, Plot B). Distribution for A is either instantaneous or does not occur. The V_d (volume/mass) is calculated: $V_d = Dose/C_o$. For drugs distributed into peripheral tissues, at least two components are present (Plot B). PDC decline in the first phase due to both distribution into tissues and elimination. Once a distribution equilibrium has been reached, PDC decline only due to elimination (second component). Linear regression yields the equation for a two compartment open model: $\mathbf{C} = Ae^{-\alpha t} + Be^{-\beta t}$. The slope (α) is the distribution rate constant whereas the slope of the second (terminal) component is the elimination rate constant (β or k_{el}). The V_d of the central compartment for such a drug is calculated from PDC extrapolated to the y intercept from the first component prior to distribution (A) and the V_d of the peripheral compartment from the y intercept of the second component (B, after distribution equilibrium is reached). For oral administration (Plot C), absorption generally also follows first order, and the general equation becomes $C = Be^{-\alpha t} - Ae^{-kat}$ (the absorption component is subtracted from the remainder of the curve). The absorption rate constant (k_a) can be derived from the upswing of the curve, but only after the elimination component of the curve is stripped. Generally, the distribution phase of non-IV doses is masked by the absorptive phase. Bioavailability *(F)* of the drug would be determined from the ratio of area under the curve measured from data collected

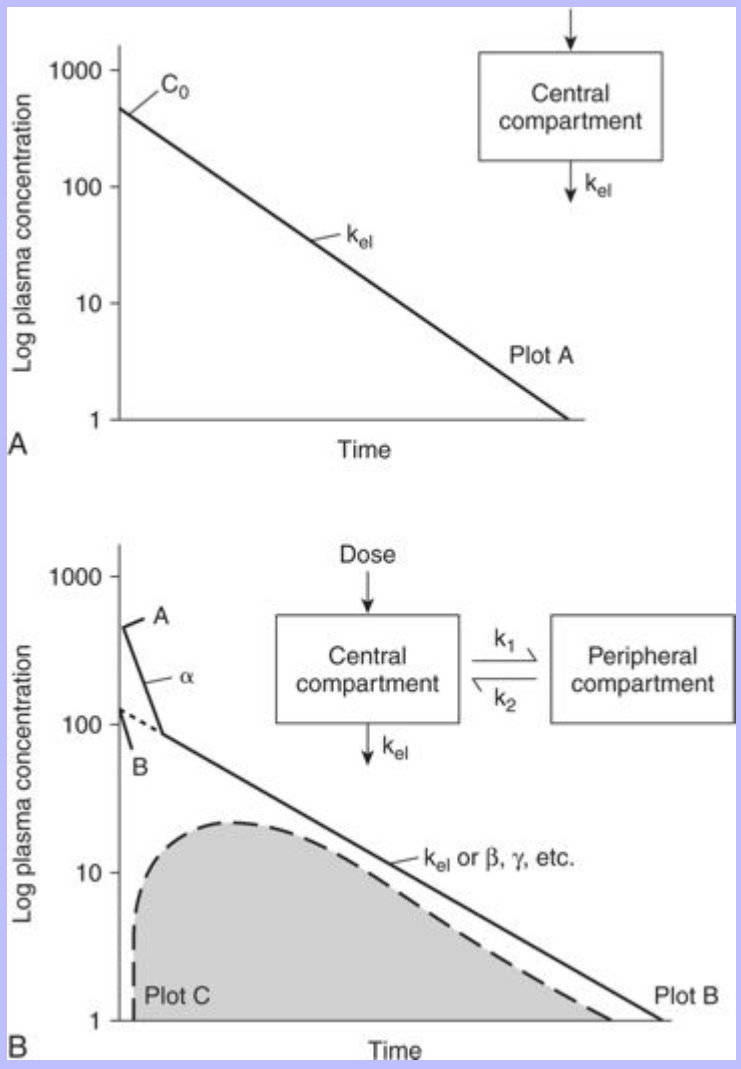
after administration of the extravascular dose *(dotted line)* and the IV dose. The AUC for each route must be adjusted for any dose differences: $F = AUC_{oral} \times Dose_{oral}/AUC_{IV} \times Dose_{IV}$.



The dose of drugs not administered IV is based on the *bioavailability,* or the percent of administered drug that reaches systemic circulation *(F)*. Bioavailability is calculated by comparison of the area under the PDC versus time curve *(AUC)* generated from data collected following administration both IV (defined as 100% bioavailable) and the alternative route being studied (Figure 134-2, *C*). If the AUC for both curves are equal following adjustment for dose differences, bioavailability is 100% (F = 1.0). However, the pharmacologic response to a drug may vary even if bioavailabilities are equal. A drug whose rate of absorption is slower than another may be completely absorbed (i.e., bioavailability is 100%), but PDC may not reach the same magnitude or peak when in a different preparation.

Subjecting PDC across time may force the data to fit a model that is not appropriate. Non-compartmental (model independent) analysis describes drug behavior based on statistical moments, area under the time versus concentration curve (AUC), and area under the moment curve, which are generated from computer analysis. Elimination half-life is based on the slope of the terminal component of the curve. However, a comparable parameter, mean residence time (MRT), which describes the time needed for 63% of an IV dose to be eliminated, is more physiologically relevant.

134.2.1.2 Mechanisms of Drug Movement

Each drug movement is affected by a number of physiologic factors, the most important being the rate and extent of passive diffusion. Lipid solubility, molecular weight, and drug pK_a are major determinants of passive diffusion that reflect the chemical structure of the drug and thus cannot be modified. The concentration gradient of diffusible drug across the site of drug movement is the single most important determinant of passive drug diffusion; thus passive drug movement is most simply increased by increasing drug dose. However, the amount of diffusible drug can be influenced by many factors, particularly dissolution and ionization. In its ionized form, a drug cannot traverse lipid membranes and may be "trapped" in the environment. A weakly acidic drug is generally ionized when surrounded by an environmental pH that is greater than its pK_a (i.e., a basic environment) or, if a weak base, less than its pK_a (i.e., an acidic environment). Thus orally administered aminoglycosides (pk_a 9 to 10) are ionized and trapped in the acidic environment of the gastrointestinal tract, whereas as weak acids, such as the betalactam antibiotics (e.g., amoxicillin or cephalothin) will be predominantly unionized and more likely to be well absorbed (if not destroyed by gastric acidity). Likewise, aminoglycosides are less effective in an acidic urine compared with an alkaline urine, although they will be more rapidly eliminated. Beta lactams, however, will be unionized in an acidic urine, and as such, they not only will penetrate bacteria more easily but they are more likely to be passively reabsorbed from the renal tubular lumen and hence "recycled" before being eliminated in the urine. Other host determinants of passive diffusion include thickness of the membrane to be traversed (i.e., edematous compared with normal tissues); surface area (e.g., small intestine versus stomach); and temperature.

134.2.1.3 Determinants of Drug Disposition

134.2.1.3.1 Absorption

Both rate and extent of absorption from the gastrointestinal tract are influenced by a number of host factors, most of which affect passive diffusion. These include gastrointestinal pH, which favors absorption of weak acids; surface area, which favors absorption in the small intestine instead of the stomach; motility, which mixes the drug, thus increases the concentration of diffusible drug at the site of movement; permeability and thickness of the mucosal epithelium, which can be negatively or positively impacted by disease; and, less commonly, intestinal blood flow, which maintains the concentration gradient across the mucosal epithelium. The latter factor is important only for drugs capable of rapid transfer across the epithelium. Other factors such as the impact of acidity on product stability or the presence of p-glycoprotein in intestinal epithelial cells (e.g., for cyclosporine) can also affect gastrointestinal drug absorption. Bioavailability of an orally administered drug also is decreased if the drug is metabolized by intestinal epithelial cells (e.g., again cyclosporine) or microbes, or the liver. Hepatic metabolism can profoundly affect systemic delivery of an orally administered drug because absorption into the portal vein exposes the drug to the liver prior to systemic circulation. Drugs

characterized by a high hepatic extraction ratio (>70%) are almost completely removed from the blood by hepatocytes during the first passage of blood through the liver (first-pass metabolism). Oral doses of such drugs must be increased despite good to excellent oral absorption if PDC are to be therapeutic. The effects of first-pass metabolism may be reduced if drug metabolites are also pharmacologically active (i.e., propranolol and diazepam).

Novel routes of drug administration may overcome the detrimental effects of first pass metabolism of some drugs. Examples include transdermal delivery such as patches, ointments, or gels; buccal patches and iontophoresis; aerosolization; and rectal administration. However, before a novel route is accepted as an effective method of drug delivery by the medical community, it must be scientifically established for the drug, as is exemplified by the use of transdermal gels for systemic delivery of drugs in cats, which have been proven effective following single-dose administration of several days.

134.2.1.3.2

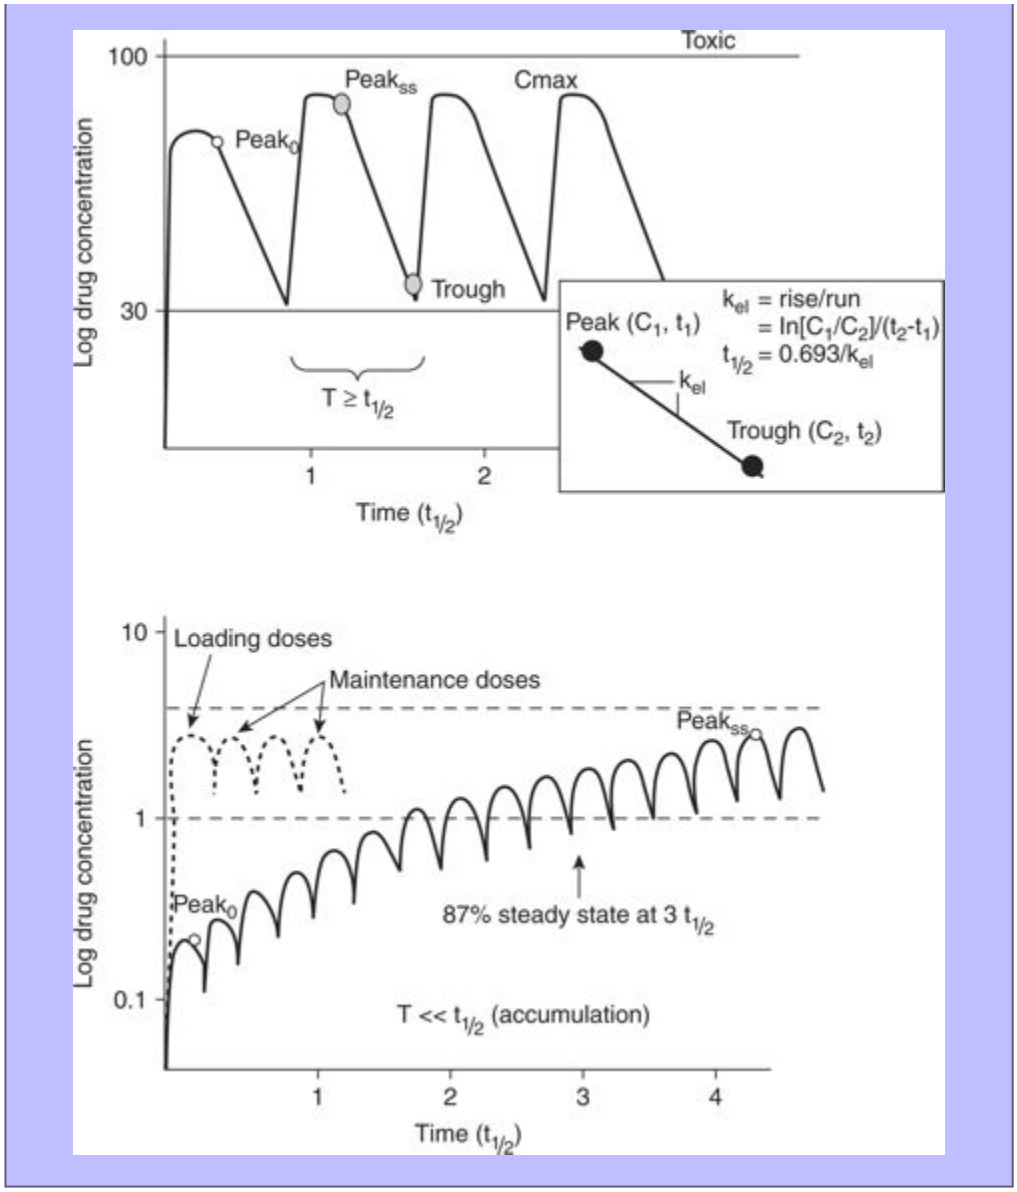
Distribution

Once a drug reaches systemic circulation, it must be distributed from the central (blood) compartment to the site of drug action in peripheral tissues and then back into the central compartment to be eliminated (see Figure 134-2). Because C_{max} (Figure 134-3) is not achieved in tissues until distribution has reached equilibrium, peak drug monitoring samples should not be collected immediately after dosing. The major factors that determine drug distribution include lipid solubility of the drug (its ability to penetrate cell membranes); concentration of diffusible drug (thus not bound to proteins or other tissue components), and regional (organ) blood flow. The lipid solubility of the drug influences the extent of protein binding as well as the extent of drug distribution, and thus V_d and dose. Although V_d is useful for determination of doses and extent of distribution, it cannot confirm where the drug has been distributed. However, lipid soluble drugs distribute to total body water. As such, they are characterized by a V_d ε 0.6/kg. A V_d of this magnitude suggests that the drug is distributed to total body water because it can penetrate cell membranes, which might be an important consideration in selection of some drugs (e.g., antibiotics, drugs active in the central nervous system). In contrast, the distribution of water-soluble drugs is limited to extracellular fluid (ECF) and V_d for such drugs generally is 0.3 L/kg or less. If the V_d of a drug changes due to disease (or varies among species), the dose of drug necessary to get the same PDC must similarly change. For lipid soluble drugs. as weight increases, the V_d of the drug will proportionately change with weight and dosing on a mg/kg basis is appropriate. However, predicting the effect on water-soluble drug is more difficult. Pediatric patients are characterized by an ECF compartment that is proportionately greater than that in adults. Thus doses of water-soluble drugs should be higher for them compared with adults. Diseases associated with fluid retention (ascites, edema) or intensive fluid therapy are likely to increase V_d of many water-soluble drugs (and thus decrease PDC), whereas obesity, dehydration, or weight loss is likely to decrease V_d and thus increase PDC of a water-soluble drug. Dosing based on body surface area (i.e., mg/m^2) may also avoid increased risk of adverse events that occur in some patients due to differences in body size. This method of dosing also takes into account differences in excretion. However, this method may increase the risk of toxicity in very small animals (<10 kg).

494

495

Figure 134-3 The goal of a fixed dosing regimen is to maintain PDC in the therapeutic range after multiple extravascular dosing. The therapeutic range of a drug is defined by a peak or maximum concentration (C_{max}) above which toxicity is more likely, and a trough or minimum concentration (C_{min}) below which therapeutic failure is more likely. A drug whose dosing interval is longer than its half-life *(A)* will be largely eliminated before the next dose is given. The fluctuation in PDC can be unacceptably large for such drugs. In contrast, a drug administered at an interval shorter than its half-life *(B)* will accumulate since most of the drug is still in the body by the next dose. At steady-state, which occurs at 3 to 5 drug half-lives, the fluctuation in drug concentrations during the dosing interval is small. For any drug, half-life can be determined from peak (C_{max}) and trough (C_{min}) P (*inset*, **B**). Since the PDC is plotted logarithmically, the equation for slope (rise over run) becomes: ln $[C_1/C_2]/t_2$-t_1. For example, if gentamicin samples collected at 2 hours and 12 hours after an IV dose were 10.5 and 2.0 µg/ml, the k_{el} for gentamicin in this animal would be 0.17 hr^{-1}, where C_{max} and C_{min} are the desired peak and trough concentrations, respectively. Since C1/C2=2 at one $t_{1/2}$ (where t_2-t_1= $t_{1/2}$), $t_{1/2}$= 0.693/k (0.693-natural log [Ln] of 2). For gentamicin in this example, the elimination half-life would be $0.693/0.17^{-1}$hr or 4.2 hr. If a dosing interval is deemed inappropriate, a more appropriate interval (T_{max}) can be calculated: T_{max}= ln$[C_{max}/C_{min}]k_{el}$.



Drug binding to proteins affects distribution. Plasma protein-binding renders a drug more water soluble, which facilitates movement in circulation. Weakly acidic, lipid-soluble drugs tend to bind to albumin, whereas basic drugs tend to bind to α_1 glycoproteins. Drugs also may bind to tissue proteins. However, the protein-bound drug cannot be distributed between plasma and tissues. Protein-bound drug is not pharmacologically active, cannot be renally excreted, and for many drugs, does not distribute into hepatocytes responsible for hepatic metabolism. Highly protein-bound (>80%) drugs are more likely to be involved in adverse drug events because displacement of only a small proportion of drug from the protein (i.e., due to competition with other protein-bound drugs, or hypoalbuminemia) can significantly increase the proportion of free, active drugs. For example, displacement of only 1% of a drug that is *99%* protein-bound (e.g., nonsteroidal antiinflammatories) such that it becomes 98% bound doubles the

concentration of pharmacologically active drug. However, increased renal and hepatic clearance of the unbound drug will increase such that PDC eventually return to normal as a new equilibrium is reached. Highly protein-bound drugs are characterized by a V_d of less than 5%, the volume of the plasma or blood central compartment. However, displacement from plasma proteins increases the V_d of the drug as free drug enters tissues. Protein-binding of drugs complicates extrapolation of dosing regimens among species because the proportion of bound drug often is not determined. Fortunately. the majority of drugs are not highly protein-bound. Distribution of drugs into tissues also may be influenced by proteins that pump drugs out. For example, β-glycoprotein effectively removes many drugs from the CNS; deficiencies in collies and related dogs have been correlated with CNS drug toxicities.

134.2.1.3.3

Metabolism

Irreversible drug elimination from the body is the final determinant of PDC. Most drugs are eliminated by hepatic metabolism and/or renal excretion. Lipid soluble drugs often require conversion to a water soluble form to facilitate renal elimination. Metabolism most commonly occurs in the liver in one or two phases. Phase I induces a chemical change that increases water solubility and renders the drug more susceptible to phase II metabolism. Reactions include oxidation, hydrolysis, or reduction and are mediated most commonly by cytochrome P450 (microsomal) enzymes. Phase I metabolites are often inactive (e.g., phenobarbital), but can be equally, more (i.e., a pro-drug, such as enalapril), or less active (e.g., diazepam) than the parent compound. Often, the drug becomes more toxic (e.g., acetaminophen). Multiple superfamilies of P450 enzymes exist and deficiencies or increases (e.g., drug induced, genetic) in one or more P450 enzymes are increasingly recognized for their role in selected adverse drug events. Phase II is also referred to as *conjugation* because a large, water-soluble molecule is added to either the parent drug or phase I metabolite. Glucuronidation, a reaction in which the cat is deficient, is the most common phase II reaction. Addition of glutathione to a reactive metabolite is an important mechanism by which reactive metabolites can be scavenged before tissue damage occurs. Sulfonation and acetylation, the latter being a reaction in which the dog is deficient, are less common phase II reactions. With the exception of some acetylation reactions (e.g., procainamide), phase II metabolites are inactive. Metabolites are generally eliminated in the urine, or less commonly, in the bile. Drug metabolism also occurs in other tissues, including the kidney, lungs, skin, and intestines. Drug-induced toxicity in these organs may reflect their metabolic capacity.

495

496

Factors that can affect hepatic drug metabolism include the amount and activity of drug metabolizing enzymes, and if the drug is characterized by a high extraction ratio (>70%; “flow-limited” drug), hepatic blood flow. Changes in protein-binding of highly bound drugs can also affect the rate of hepatic metabolism of drugs characterized by a low (<70%: “capacity-limited” drug) extraction ratio. The rate of elimination of capacity-limited drugs is inversely proportional to their degree of protein binding. Disease, drug interactions, and species differences can have a profound impact on drug metabolism and thus duration of drug elimination. For example, drugs that induce (phenobarbital, rifampin) metabolism increase the clearance of other drugs metabolized by the liver and can cause therapeutic failure, or possibly increased toxicity (due to metabolite formation) with the other drug. Induction generally requires multiple days of therapy and reflects an increase in the synthesis of enzymes. In contrast, inhibition can occur immediately, often due to competition for the same enzymes. Inhibitors (e.g., chloramphenicol, cimetidine, ketoconazole) will prolong the half-life of other drugs and may result in drug toxicity. Inhibitors can be used therapeutically as is exemplified by the use of cimetidine to decrease the toxicity of acetaminophen or ketaconazole to prolong the half-life of cyclosporine.

134.2.1.3.4 Renal and Biliary Excretion

Renal excretion is the most important route of drug elimination for both parent drugs and their metabolites. Host factors that determine renal excretion include glomerular blood flow, active tubular secretion, and tubular resorption, each of which is directly influenced by renal blood flow. The kidney is also capable of metabolizing some drugs, although this capacity is only occasionally of clinical importance.

Glomerular filtration is a passive process. Drugs enter the glomerulus by bulk flow, being excluded if too large (>60,000 MW), such as occurs if the drug is protein-bound. In contrast, active transport of drugs in the proximal tubules is very efficient, rapid, and independent of protein-binding. Separate transport proteins exist for acidic, basic, and neutral drugs. Transport is susceptible to competition among drugs, although drug interactions as a result of competition are not frequent and seldom clinically relevant. The prototypic example of competition is the use of probenecid to compete with and thus inhibit the renal excretion of expensive beta-lactam. Resorption of drugs from renal tubules into peritubular capillaries slows renal excretion and prolongs drug half-life. The extent to which a drug is reabsorbed depends upon its lipid solubility and its ionization. Weakly acidic drugs are more likely to be resorbed in acidic urine but are more likely to be trapped and excreted in alkaline urine. Changes in urinary pH (especially acidification) might be therapeutically altered to modify the rate of renal drug excretion. Because renally excreted drugs are concentrated in the kidney (urine), selection of antibiotics for treatment of bacterial cystitis (but not other urinary tract infections) based on minimum inhibitory concentrations (MIC) may markedly underestimate the efficacy of the drug because MIC generally are based on plasma, rather than urine, drug concentrations.

In contrast to renal excretion, biliary excretion is very slow and is much less clinically important. Drugs are eliminated in the bile by at least three active transport systems: one each for organic acids, bases, or neutral compounds. Characteristics that determine biliary excretion of drugs include chemical structure, polarity, and molecular weight (generally >600 MW); the latter is one of the major determinants. Drugs excreted in the bile are in greater contact with the intestine and its flora compared with other drugs and are thus more likely to cause adverse reactions in the gastrointestinal tract. Whereas a conjugated drug will not be resorbed from the intestinal tract, intestinal microbes can unconjugate drugs so that they are reabsorbed *(enterohepatic recirculation)*. The half-life and exposure of the drug to the intestinal tract is subsequently prolonged.

134.2.1.3.5 Elimination

The combined effects of renal and biliary excretion, as well as other routes of elimination (i.e., pulmonary, sweat) irreversibly remove drug from the body. The elimination half-life of a drug is the time necessary for half the drug to be eliminated from the body and is derived from the terminal component of the PDC versus time curve. It is one of the most useful parameters for determining an appropriate dosing interval. At one drug elimination half-life, 50% of the dose has been eliminated; by 3 to 5 drug half-lives, 87 to 99% of the drug has been eliminated. Thus for a drug with a 4-hour half-life, approximately 12 to 20 hours must elapse before most of the drug has been eliminated. For drug intoxication, 1 to 2 elimination half-lives is generally sufficient for PDC to drop below the toxic range unless a massive overdose has occurred. An exception occurs if hepatic drug (or other) metabolizing enzymes become saturated. In such cases, elimination becomes zero order and half life is no longer an applicable parameter.

Plasma clearance (CI) is the volume of plasma irreversibly cleared of the drug per unit time and represents the sum total of organ clearance. Unlike elimination (a rate), clearance is a volume per unit time. The volume of blood cleared per unit time by an organ is independent of PDC. The same volume of blood will be irreversibly cleared of drug by an organ regardless of how much drug is in the blood. If the drug is cleared exclusively by one organ (e.g., renal clearance of aminoglycosides or hepatic clearance of caffeine), then plasma clearance also represents clearance of the specific organ and can be used to evaluate the function of the organ. Although clearance is the physiologic activity responsible for drug elimination, it generally is not directly measured, but rather, is calculated from other parameters (see Figure 134-2). However, it can be determined only after IV administration. The impact of changes in clearance tends to be estimated by changes in elimination half-life. However, although half-life is the clinically useful estimate of how long a drug stays in the body, it is a "hybrid" parameter in that it is influenced by both distribution and clearance. The greater the volume of drug cleared per unit time, the shorter the drug half-life. However, the larger the V_d, the longer the half-life because the distributed drug cannot access the organs of clearance. Thus drug elimination half-life changes directly (and proportionately) with the volume of distribution of a drug but inversely (and proportionately) with the clearance of the drug. The clinical significance of these relationships might be exemplified in a patient that has become dehydrated as a result of uncompensated chronic renal disease. As tissue volume contracts with dehydration, the V_d decreases. Although PDC (and the risk of drug toxicity) increases, because the volume cleared per unit time does not change, and because more drug is in each milliliter of blood, the drug is actually eliminated more rapidly. If all else remains normal, drug half-life will decrease. In the patient that is not dehydrated but suffers from significantly comprised renal function, renal clearance decreases and drug half-life thus also decreases. In the patient with both volume contraction due to dehydration and compromised renal function, the effects of the changes in clearance and volume of distribution balance one another. Drug elimination half-life may not change, even though renal function may be impaired. With successful volume replacement, half-life may increase unless renal function also improves.

496

497

134.3 FIXED DOSING REGIMENS

134.3.1 Dose

A fixed dosing regimen is comprised of a dose and interval. The dose necessary to achieve a specified target PDC (e.g., C_{max}) depends on the V_d:

$$\text{Dose} = [C_{max}][V_d]$$

The dose of drug must be increased or decreased proportionately with changes in V_d to achieve the same target PDC. The V_d of a drug is the sole determinant of PDC achieved after an IV dose is administered for drugs that do not accumulate (i.e., the dosing interval is sufficiently long that each dose is essentially eliminated before the next dose; see below). For drugs that do accumulate, the initial dose of the drug must also take into account the magnitude of accumulation, which is in turn dependent upon the elimination half-life of the drug in relation to the dosing interval.

134.3.2 Interval

The frequency of dosing or the dosing *interval* is determined by the time (T_{max}) it takes for maximum PDC (C_{max}) to drop to a point below which the desired response no longer occurs, C_{min} (Figure 134-3, *A*). Thus T_{max} depends on the amount of fluctuation in PDC desired during the dosing interval and the elimination rate constant (k_{el}). If C_{min} for a drug is close to half of C_{max}, then approximately 1 drug half-life (i.e., $T_{max} = t½$) can elapse before the next dose must be administered. A more appropriate interval can be calculated using k_{el} if C_{min} does not approximate half of C_{max}. The longer the elimination half-life of a drug, the longer the interval (or T_{max}) can be between doses.

Decreasing a dosing interval is of no benefit for drugs whose half-life is long. For example, an 8-hour dosing interval for phenobarbital (drug half-life 50 to 100 hours average 72 hours) offers no advantage to a 12-hour interval since very little drug will be eliminated during the 12-hour period between doses. An exception is made if induction of drug metabolizing enzymes by phenobarbital has decreased drug half-life to less than 24 hours. In contrast, prolonging a dosing interval for convenience may be dangerous for drugs with a short half-life (e.g., many antibiotics). For example, if the drug half-life is two hours, a 4-hour increase in the dosing interval will result in a *75%* decrease in C_{min} since 2 half-lives will elapse between the dosing interval. For drugs with a short half life, often adding an additional dose (i.e., shortening the dosing interval) is more effective (and cheaper) than doubling the dose. An example might be a time dependent (betalactam) antibiotic or cyclosporine. Some drugs remain effective despite dosing intervals that are longer than the elimination half-life of the drug. Examples include antimicrobials that exhibit a post antibiotic effect (e.g., aminoglycosides); drugs that accumulate in tissues (e.g., omeprazole); drugs whose metabolites are active (particularly if the metabolite half-life is longer than the parent compound [e.g., tepoxalin]); and drugs that destroy targets that must be resynthesized before the effect resolves (e.g., selected antiprostaglandins).

Drug half-lives can be as short as 2 minutes or less (e.g., epinephrine and dobutamine) or as long as several weeks (e.g., potassium bromide). Drugs with half-lives that are too short for convenient dosing are either given as constant IV infusion (e.g., lidocaine) or may be prepared as slow-release preparations (e.g., benzathine penicillin). Although the elimination half-life of the drug does not vary for slow release preparations compared with other preparations of the drug, the absorption of the drug is much slower. The intent, although not always successful, is to maintain constant therapeutic concentrations by ensuring continuous addition of drug into plasma. Note, however, that absorption may be so slow that therapeutic concentrations are never reached. Many oral drugs are prepared as slow-or continuous-release preparations (e.g., quinidine or theophylline). However, these preparations have been formulated for humans and the release kinetics may vary substantially in animals. Use of these preparations should be reserved for drugs that have been studied in animals. Alternatively, therapeutic drug monitoring for some drugs can be used to ensure that drug concentrations fall within the therapeutic range.

134.3.3 Accumulation

For drugs with very long half-lives, the dosing intervals can be correspondingly prolonged to allow for convenience. However, a dosing interval that is too long is also often inconvenient (e.g., phenobarbital and 3 days). In addition, for drugs with a narrow therapeutic range, fluctuation of PDC during the dosing interval must be minimized. In both situations, the recommended dosing interval (e.g., every 12 hours for phenobarbital) may be shorter than the drug elimination half-life. With each subsequent dose of drug administered at an interval *(T)* that is shorter than drug half-life, drug from the previous dose will remain in the

body. The amount of drug remaining depends upon how much shorter the dosing interval is compared with the half-life. In such situations, the drug begins to accumulate with multiple doses (see Figure 134-3, *B*). Eventually, a steady-state is reached for the drugs such that the amount of drug administered with each dose equals the amount eliminated during the dosing interval. As with drug elimination, approximately 3 to 5 drug half-lives must elapse following a fixed dosing regimen before steady-state is reached. Steady-state is a relevant issue only for drugs that accumulate. The amount that a drug will accumulate as steady-state is reached depends on the difference between drug elimination half-life and the dosing interval. The greater the difference (the larger half-life is compared with the interval), the more the accumulation. For example, bromide (half-life 21 days) will accumulate more than phenobarbital (half-life 3 days) when both are administered twice daily. The amount of accumulation can be approximated. If the elimination half-life is equal to dosing interval, drug will accumulate twofold; if the elimination half-life is twice the interval, concentrations at steady state will accumulate fourfold. The relationship between elimination half-life and dosing interval also determines the amount that PDC may fluctuate during a dosing interval. The larger the elimination half-life compared to the dosing interval, the smaller the fluctuation in PDC during a dosing interval. For drugs administered at an interval equal to the elimination half-life, PDC will fluctuate twofold between doses. The relationship between drug half-life and dosing interval also influences the number of samples collected for therapeutic drug monitoring. For drugs with a long half-life (compared to the closing interval), a single sample (often trough) may be sufficient (e.g., bromide, often phenobarbital), whereas both peak and trough samples are indicated for drugs with a short half-life (e.g., digoxin) that allows fluctuation during the dosing interval.

Drugs that accumulate protect the patient in that PDC are stable (i.e., do not fluctuate during a dosing interval). 497
However, drugs that accumulate also present problems that are not encountered with drugs administered at an 498
interval that precludes accumulation. Maximum therapeutic efficacy will not be realized until steady-state concentrations have been reached, which may be an unacceptable time for some patients (i.e., epileptics receiving potassium bromide which has a 21 to 24 day half-life in dogs). In such situations, a loading dose can be administered. This single dose, based on bioavailability and V_d of the drug and target concentrations (usually between C_{max} and C_{min}),

$$\text{Dose} = C^{*}V_d/F,$$

is intended to achieve therapeutic concentrations with the first dose. A disadvantage to loading dose is that the body cannot gradually adapt to the drug. Additionally, the maintenance dose may not maintain PDC reached by loading. In such cases, PDC may gradually decrease below C_{min} *or* increase above C_{max} and the change may not be evident until a new steady-state has been reached 3 to 5 drug half-lives later. For bromide, monitoring immediately after a loading dose and at one month (1 half-life) allows proactive evaluation of the maintenance dose. If the two concentrations are not similar, the maintenance dose can be appropriately modified. For drugs that accumulate, the addition of a single maintenance dose of the drug to the total amount of drug in the patient's body at steady state can be considerably small, and multiple doses (i.e., a small loading dose) must be given to immediately influence PDC. Alternatively, the maintenance dose will need to be increased and a new steady state reached 3 to 5 drug half-lives later.

134.3.4 Therapeutic Range

The therapeutic range provides a target for the dosing regimen and is designed to generate therapeutic but not toxic concentration at the tissue site. Fixed dosing regimens comprise a dose (e.g., mg/kg) and an interval (e.g., every 8 hours) that should result in PDC in the therapeutic range throughout most of the dosing interval. The therapeutic range generally consists of a minimum effective PDC (trough or C_{min}), below which therapeutic failure is likely to occur; and a maximum effective PDC (peak or C_{max}), above which a type A adverse reaction

is more likely (see Figure 134-1). However, a therapeutic range is a population statistic and targets concentrations between which a large proportion (e.g., 95% of the population) will respond. A small percentage of animals will respond above or below the therapeutic range whereas others will exhibit clinical signs of toxicity below the maximum therapeutic range. When possible, therapeutic drug monitoring should establish the therapeutic range for the individual patient. The most appropriate therapeutic range for a drug as a target is complicated the class and intent of the drug. For example, therapeutic ranges for antimicrobials are based on the microorganism (e.g., immune-inhibited) and whether or not the antimicrobial is a time (e.g., beta-lactamase) versus concentration (e.g., aminoglycosides) dependent drug. The therapeutic range for digoxin is greater if improved contractivity is the target as opposed to decreased heart rate.

135 CHAPTER • 135 Antimicrobial Drug Therapy

Mark G. Papich

Tara Bidgood

The administration of antimicrobials to animals is among the most common treatments in veterinary medicine. The development of new drugs, revised approaches to dosing, and the emergence of resistant bacteria have modified this approach to therapy. The intent of this chapter is to discuss the important factors that guide and affect antimicrobial drug therapy in animals. Although "antimicrobial therapy" encompasses other aspects of therapy, such as antifungal, antiparasitic, and antiviral therapy, this chapter focuses on antibacterial therapy.

135.1 STRATEGIES FOR SELECTION OF AN APPROPRIATE ANTIBIOTIC

135.1.1 Empirical Drug Selection

Initial bacterial therapy can be instituted for many infections based on the presumptive activity of drugs against the bacteria and the historical performance (or in some instances anecdotal performance) of available drugs. Prescribing empirically is more reliable when resources provide guidelines on the susceptibility of bacteria, or clinical trials predict efficacy. Several surveys have been published and drug manufacturers have provided susceptibility information on their package inserts that is helpful. Based on this information, some general guidelines are possible:

If the bacteria is suspected to be a streptococci (but not *Enterococcus* spp.), β-streptococci, or *Bacillus*, *Actinomyces,* or *Pasteurella* spp., successful therapy can be achieved by administration of a penicillin such as ampicillin, or amoxicillin, amoxicillin + clavulanate (e.g., Clavamox), a tetracycline, or trimethoprim-sulfonamide. Other drugs also may be effective, but the more expensive, newer drugs or injectable agents might be considered overkill for such susceptible bacteria.

Staphylococcal infections in small animals are usually caused by *Staphylococcus intermedius*. Susceptibility can be expected to first-generation cephalosporins (e.g., cephalexin, cefadroxil, or cefazolin), amoxicillin-clavulanate (Clavamox), clindamycin, or one of the fluoroquinolones (e.g., enrofloxacin, difloxacin, marbofloxacin, or orbifloxacin). All of these drugs have been effective in clinical trials.

Gram-negative bacteria are more likely to develop resistance. Gram-negative bacilli of the Enterobacteriaceae (e.g., *Escherichia coli, Klebsiella pneumoniae*, and *Enterobacter* spp.) are resistant to many of the commonly used first-line drugs such as amoxicillin, ampicillin, tetracyclines, and first-generation cephalosporins (e.g., cephalexin, cefadroxil). Published studies have shown that the proportion of these bacteria resistant to these drugs can exceed 50%.[1–3]

Other problem bacteria include indole-positive *Proteus* spp., such as *Proteus vulgaris,* and *Pseudomonas aeruginosa*. Of the gram-positive bacteria, the problem bacteria include the enterococci, such as *Enterococcus faecium* or *Enterococcus faecalis. Staphylococcus* spp. (especially *S. aureus*) may acquire a resistance gene and become unaffected by β-lactam antibiotics, including cephalosporins. Fortunately, the prevalence of resistant staphylococci is still low in veterinary medicine.

P. aeruginosa is inherently resistant to many drugs because it lacks high-permeability porin proteins by which antibiotics gain access to bacteria. It also may produce beta-lactamase. A wild strain of *P. aeruginosa* has inherent resistance to most common drugs but should be susceptible to amikacin, gentamicin, or tobramycin, extended-spectrum penicillins (ticarcillin, piperacillin), some selected third-generation cephalosporins (e.g., ceftazidime), carbapenems (e.g., meropenem or imipenem), and perhaps a fluoroquinolone. Of the fluoroquinolones, ciprofloxacin, a human-registered drug, is the most active.

In clinical cases in which a resistant strain or bacteria with unpredictable sensitivity is suspected, a susceptibility test is advised to confirm the drug selection. But before results are available, initial therapy to treat infections caused by gram-negative enteric bacteria can be initiated with a fluoroquinolone (e.g., enrofloxacin, ciprofloxacin, difloxacin, marbofloxacin, or orbifloxacin), a cephalosporin, amoxicillin-clavulanate (e.g., Clavamox), or an aminoglycoside (e.g., gentamicin or amikacin).

If the bacteria is anaerobic, the gram-positive species such as *Clostridium* or *Actinomyces* species are susceptible to penicillins (e.g., penicillin G, ampicillin, amoxicillin), metronidazole, or clindamycin. The gram-negative anaerobes are usually susceptible to the same group of drugs except that bacteria of the *Bacteroides fragilis* group may be β-lactamase producers. In these cases, one should consider amoxicillin-clavulanate, metronidazole, clindamycin, or a second-generation cephalosporin (e.g., cefoxitin or cefotetan). Chloramphenicol also is active against anaerobic bacteria, but this drug is not as available as in previous years. The activity of first-generation cephalosporins and trimethoprim-sulfonamide combinations may be unpredictable for anaerobic infections.[4]

135.2 BACTERIAL SUSCEPTIBILITY TESTING

Bacterial susceptibility testing is recommended for cases that are not responding to antibiotic treatment, or in cases in which the suspected bacteria is known to possess a pat-tern of resistance that makes empirical drug selection unreliable. Although not perfect, susceptibility tests help refine the antibiotic selection process. If an organism tests resistant to a particular antimicrobial, the likelihood of successful therapy with that drug is diminished. On the other hand, a test that indicates susceptibility is no guarantee of clinical success.

135.2.1 Agar-Disk Diffusion Test

The most familiar test for measuring bacterial susceptibility to antimicrobials has been the Agar-Disk-Diffusion (ADD) test, also known as the Kirby-Bauer Test. Details for performing this test have been previously described.[5,6] The ADD test measures the inhibition of bacterial growth against the antimicrobial concentration from a paper disk placed on the agar. The zone size is roughly correlated to the minimum inhibitory concentration (MIC). The larger the zone size, the lower the MIC, and vice versa. Since each antibiotic diffuses at different rates throughout the agar, use published standards for interpreting the sensitivity.[6]

135.2.2 Dilution Test for MIC Determination

The dilution test directly measures the MIC. This test is now available in many veterinary microbiology laboratories. It is a more quantitative measurement of susceptibility, and the test better correlates with clinical efficacy. The interpretation of the MIC test relies on knowing the breakpoints for each drug. Some selected MIC breakpoints[6] for bacteria are shown in Table 135-1.

135.2.2.1 Interpretation of Susceptibility Information

The interpretation uses the "SIR" system, which is sensitive, intermediate, and resistant. If the MIC is below the suscepti-ble breakpoint, the organism is sensitive and a cure can be expected using standard doses. If the MIC is above the resistant breakpoint, the organism is resistant and drug therapy with that drug is not recommended. MIC values between resistant and sensitive categories fall in an "intermediate" zone. (This also has been called "moderately susceptible.") If the MIC is intermediate, the organism should ordinarily be considered resistant. However, successful therapy can be achieved when the drug concentrates at high levels as it does when treating a lower urinary tract infection, or when topical therapy is used. In extreme cases, high doses have been used to achieve drug levels for organisms with susceptibility in the intermediate range, but this should not be considered unless the drug has a high therapeutic index (e.g., with the β-lactam antibiotics). For some fluoroquinolones, the intermediate interpretation was called the "flexible dose" zone, for which high doses can be considered, but the flexible dose category was recently abandoned by the NCCLS.

135.2.3 Limitations of Bacterial Sensitivity Testing

There are important limitations to consider when assessing the clinical relevance of *in vitro* antibacterial susceptibility tests. Sensitivity tests assume equal plasma and tissue concentrations and will overestimate the antimicrobial activity in tissues that may be difficult to penetrate, such as the central nervous system, prostatic fluid, and mammary gland. Sensitivity tests will underestimate activity of topical treatments, local infusions, and antibacterials that concentrate in the urine. Susceptibility tests also may underestimate activity at drug concentrations below the MIC (sub MIC effects). Sensitivity tests do not detect potentially synergistic antibiotic combinations (except for trimethoprim-sulfonamides and amoxicillin-clavulanate). An example of a synergism is the combination of a β-lactam antibiotic and an aminoglycoside. Bacteria may be resistant to either drug alone but sensitive when administered in combination. Finally, sensitivity tests cannot consider the local factors that may affect antimicrobial activity such as pus, necrotic tissue, low oxygen tension, and poor blood perfusion. For example, an aminoglycoside may not be effective *in vivo* if the infection is in necrotic tissue or an abscess, despite an *in vitro* test that indicates susceptibility. Likewise, the activity of fluoroquinolones is decreased in an acid environment, or one in which there are cations present (e.g., Mg^{++}, Ca^{++}), such as urine. In these instances, even when the MIC is in the "susceptible" range, the organism may be resistant *in vivo*.

Table • 135-1 Minimum Inhibitory Concentrations (MIC) Breakpoints

ANTIMICROBIAL	SUSCEPTIBLE (µg/mL)*	RESISTANT (µg/mL)
Amikacin	≤16	≥64
Ampicillin	≤8†	≥32
Ampicillin/clavulanic acid	≤8/4†	≥32/16
Cefazolin	≤8	≥32
Cefotaxime	≤8	≥64
Ceftazidime	≤8	≥32
Cephalothin‡	≤8	≥32
Cefoxitin	≤8	≥32
Chloramphenicol	≤8	≥32
Ciprofloxacin	≤1	≥4
Clindamycin	≤0.5	≥4
Difloxacin	≤0.5	≥4
Enrofloxacin	≤0.5‖	≥4
Erythromycin	≤0.5	≥8
Gentamicin	≤2	≥8
Imipenem (and meropenem)	≤4	≥16
Marbofloxacin	≤1	≥4
Orbifloxacin	≤1‖	≥8
Oxacillin¶	≤2	≥4
Rifampin	≤1	≥4
Tetracycline	≤4	≥16
Ticarcillin	≤64†	≥128
Trimethoprim/sulfa	≤2/38	≥4/76
Vancomycin	≤4	≥32

For ampicillin, susceptibility for staphylococci and streptococci is ≤0.25 µg/mL;
For amoxicillin/clavulanate, susceptibility for staphylococci is ≤4/2 µg/mL;
For ticarcillin, susceptibility for *Pseudomonas* spp.is ≤64 g/mL for, *Pseudomonas* spp., and ≤16 g/mL for enteric gram-negatives;
For erythromycin, susceptibility for streptococci is ≤0.25 g/mL.

* Values between the susceptible and resistant range are interpreted as "intermediate."

† There are exceptions for interpreting some pathogens.(See NCCLS, 2002 for details.)

‡ Cephalothin is used as a marker to test for susceptibility to cephalexin and cefadroxil.

‖ For enrofloxacin and orbifloxacin, the "intermediate" category may require higher doses.

¶ If organisms are resistant to oxacillin, they should be considered resistant to other β-lactam antibiotics also.

135.3 DESIGNING OPTIMAL DOSING REGIMENS

Pharmacodynamics refers to the action of the drug on the bacteria (i.e., if it is bactericidal, bacteriostatic, time-dependent killing, concentration-dependent killing). *Pharmacokinetics* describes the disposition of drug in the body and forms the profile of the drug concentration versus time in the body. The pharmacokinetic-pharmacodynamic (PK-PD) relationships are used to define optimal dosing guidelines for antibiotics in animals. To accomplish this, the pharmacokinetic profile is defined according to its relationship to the MIC.

PK-PD relationships have been correlated to certain variables such as the peak plasma concentration (C_{MAX}), the area of the plasma concentration versus time curve (AUC), and the length of time that the plasma concentration is above the MIC (T>MIC) during a 24-hour interval. These relationships are shown graphically in Figure 135-1. Antibacterial drugs have been described as either bacteriostatic or bactericidal. Bacteriostatic drugs inhibit bacteria, but growth may resume when the drug concentration falls below the MIC. Bactericidal drugs kill the bacteria if the drug concentration is high enough above the MIC, or if the MIC is exceeded for a long enough time. Bactericidal drugs may be either time-dependent in their killing or concentration-dependent. The optimal dosage regimens for classes of drugs can be devised by consideration of these relationships.

135.3.1 Bacteriostatic Drugs

Drugs considered bacteriostatic include tetracyclines, macrolides (erythromycin), azithromycin, sulfonamides, and clindamycin. Under most conditions, chloramphenicol also is bacteriostatic. For these drugs, optimum therapy is achieved by using dosage regimens that maximize the drug concentration above the MIC throughout the dosing interval. Therefore, all bacteriostatic drugs are considered time-dependent (T>MIC). For drugs in this group, if they do not have long half-lives, they must be administered frequently to achieve this goal. Some of the macrolide antibiotics, such as azithromycin, achieve this goal because the drug concentrations persist in tissues much longer than in the plasma after dosing.

135.3.2 Bactericidal Drugs

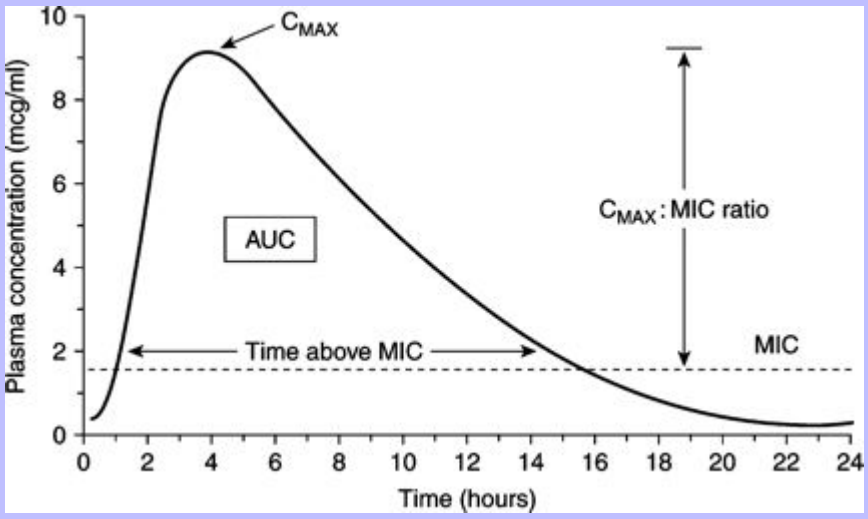
For the *time-dependent* bactericidal drugs, clinical efficacy is achieved when the time of drug concentration above MIC is maximized (T>MIC). The time-dependent drugs include the β-lactam antibiotics such as penicillins, potentiated-aminopenicillins (e.g., amoxicillin-clavulanate), and cephalosporins. There is a threshold of four to five times the MIC, above which increased bacterial killing is not observed. Therefore the most effective treatment is expected with these drugs when they are administered at more frequent intervals, rather than by increasing the dose. A constant rate infusion, although impractical in many veterinary settings, would be the most optimal. For intermittent dosing, the optimum duration of time above the MIC has not been determined for all bacteria, but in general, the T>MIC should be at least 50% of the dose interval in the non-neutropenic patient. Since most penicillins and cephalosporins in small animals have elimination half-lives of only 1 to 2 hours, dosage regimens should consider these pharmacokinetic-pharmacodynamic relationships. When a gram-negative infection is treated, especially a serious one, penicillin derivatives and cephalosporins are administered at least three to four times per day for optimum results.

A few exceptions exist to these guidelines: For the specialized group of β-lactams, the carbapenems (e.g., imipenem and meropen), the T>MIC may be less than 50% because these drugs are more bactericidal. For example, meropenem can be administered twice daily for infections in small animals.[7] Secondly, since the MICs of β-lactam antibiotics are lower for some gram-positive bacteria (e.g., *Staphylococcus* spp.), and antibacterial effects occur at concentrations below the MIC, longer dose intervals may be possible compared with regimens used for other bacteria. For example, cephalexin is effective for treating infections caused by *Staphylococcus* spp. when administered only once or twice a day in dogs[8], despite a half-life of only a few hours.

For *concentration-dependent drugs,* either the peak concentration (C_{MAX}) or the area-under-the-curve (AUC) is the best predictor of clinical efficacy. Aminoglycoside antibiotics such as gentamicin or amikacin are more bactericidal when the peak plasma concentrations are 8 to 10 times above the MIC. After attaining this peak,

plasma concentrations can fall below the MIC for several hours and still achieve a cure. Current dosage regimens for these drugs are designed to produce a C_{MAX}: MIC ratio of 8 to 10 when administered only once daily. Because nephrotoxicosis associated with aminoglycosides is increased by the duration of exposure, not the peak, the once-daily regimens for these drugs are as effective, and less nephrotoxic than lower doses administered more frequently.[9]

Figure 135-1 The variables of minimum inhibitory concentration (MIC), maximum (peak) plasma concentration (C_{MAX}), area-under-the-curve (AUC) for the plasma concentration versus time profile, are used to derive the time above MIC (T >MIC), C_{MAX}: MIC ratio, and AUC: MIC ratio.



The fluoroquinolone antimicrobials (e.g., difloxacin, enrofloxacin, ciprofloxacin, marbofloxacin, and orbifloxacin) also are concentration-dependent. Although, the peak concentration (C_{MAX}: MIC ratio), has been correlated with *in vitro* bactericidal activity, the AUC: MIC ratio for a 24-hour period is probably a better predictor of clinical efficacy. Optimum therapy is achieved when this ratio is above 125, but a ratio of 50 in an immunocompetent animal is also sufficient for a clinical cure for many bacterial pathogens, especially when treating gram-positive bacteria.[10]

The AUC is proportional to the dose administered. Therefore to achieve appropriate AUC: MIC ratios, fluoroquinolones can be administered to treat highly susceptible organisms with the lowest registered dose, once daily. Susceptible bacteria of the Enterobacteriaceae usually have low MIC values in this range. For bacteria that are more resistant (i.e., the MIC values are higher, even though they are still considered susceptible), a higher dose is needed. For example, to achieve the necessary peak concentration for treating infections caused by *Pseudomonas aeruginosa,* which often has an MIC of 0.5µg/ml or higher, doses at or near the highest registered dose, once daily, may be needed.

135.4 TISSUE DISTRIBUTION OF ANTIBIOTICS

If the drug cannot reach the site of action (the tissue), even the most active drugs will be ineffective. With adequate perfusion, there is no barrier to impede diffusion of antibiotics from the vascular compartment to extracellular fluid of most tissues. Antibiotic drug concentrations in the serum or plasma will predict the drug concentration at the site of infection in the extracellular space (interstitial fluid). Pores and fenestrations in the endothelium of capillaries are large enough to allow drug molecules to pass through, unless the drug is highly protein bound in the blood. Therefore most soft tissues and bone do not present a barrier to drug diffusion as long as there is adequate blood perfusion. Only a few drugs are so highly bound that protein binding will impair their tissue penetration. Doxycycline is one of the few examples of a highly protein bound antibiotic used in small animals.

Because protein binding, rather than lipophilicity, is the most important factor for drug tissue penetration, there is no evidence for differences in efficacy among antibiotic drugs that can be attributed to differences in drug's lipid solubility. But drug diffusion can be limited when a lipid membrane (such as tight junctions on capillaries) presents a barrier to drug diffusion. These tissues include sequestered sites such as the central nervous system and eye, the epithelial lining fluid of the lung, and glandular tissues such as the prostate and mammary gland. To treat infections in tissues for which there is a permeability barrier, a drug must be sufficiently lipid soluble to diffuse through the lipid barrier or penetrate via carrier-mediated transport.

An example of a sequestered site is the central nervous system (CNS), which generally restricts poorly-lipid soluble and polar antibiotics. Most cephalosporins (except those classified as third generation), penicillins, and aminoglycosides do not attain adequate antibacterial concentrations in the central nervous system when administered systemically. Antibiotics with better penetrating ability include metro-nidazole, chloramphenicol, trimethoprim, and the third-generation cephalosporins such as cefotaxime. If more polar, less lipophilic drugs are used for treating CNS infections, high doses must be given to attain effective antibacterial concentrations.

135.5 TREATMENT OF SPECIFIC INFECTIONS

135.5.1 Skin and Soft-Tissue Infections

The most important skin pathogen in dogs is *Staphylococcus intermedius*. Other bacteria identified usually are opportunistic. Other staphylococci have been identified (e.g., *Staphylococcus aureus*) that are often more resistant. Wound infections or skin-fold infections may be caused by *Pseudomonas aeruginosa* or bacteria of the Enterobacteriaceae (*Escherichia coli, Klebsiella* spp., and *Proteus* spp.). Anaerobic bacteria, including *Actinomyces* spp., have been isolated from deep infections. Bacteria causing skin or other soft-tissue infection in cats induced by a bite wound can be *Pasteurella* spp., streptococci, or other inhabitants of the oral cavity, including anaerobes.

Since most skin and soft-tissue infections are extracellular, the most important feature of drug delivery is to ensure there are sufficient antibiotic drug concentrations in the extracellular fluid. As discussed previously, adequate concentrations in plasma usually ensure effective concentrations in these tissues. When purulent infections are treated, drug activity can be diminished by wound or tissue components. For example, pus may bind and inactivate certain drugs and a necrotic environment with cellular debris may inhibit activity of aminoglycosides and trimethoprim-sulfonamides. This issue may be important when treating an infection associated with an abscess or when treating otitis.

501 502

For treating infections caused by *Staphylococcus* species, the *in vitro* incidence of resistance is lowest for first-generation cephalosporins (e.g., cefadroxil, cephalexin), β-lactamase inhibitor combinations (e.g., amoxicillin-clavulanate), and fluoroquinolones (e.g., enrofloxacin, difloxacin, marbofloxacin, orbifloxacin). Other drugs that have a somewhat higher incidence of resistance but have been used successfully include erythromycin, lincomycin, clindamycin, and trimethoprim-sulfonamide or ormetoprim-sulfonamide combinations. After treatment with these drugs, resistance can be acquired, especially in cases of recurrent pyoderma.

135.5.2 Urinary Tract Infections

The most common bacteria in dogs and cats causing urinary tract infections (UTIs) are gram-negative bacilli such as *E. coli, Klebsiella,* and *Enterobacter* species. *Proteus mirabilis* and *P. aeruginosa* also may be isolated. Of the gram-positive bacteria causing infections, *Staphylococcus* spp. and streptococci are the most common. Occasionally enterococci cause infection of the urinary tract in dogs and cats, although this is usually an opportunistic pathogen of low virulence.

Treatment considerations include the antibiotics that are excreted via renal mechanisms and concentrate in the urine. These drugs include any of the penicillins and cephalosporins, tetracyclines (except doxycycline), fluoroquinolones, aminoglycosides, and trimethoprim-sulfonamides. These drugs are concentrated 10-to 100-fold in the urine compared with the plasma. Therefore it is possible to attain high drug concentrations in urine and good treatment success unless the infection is complicated by an underlying problem. Dose rates administered usually can be at the lower end of a dose range because of the concentrating effect of antibiotic in the urine. Empirical selection of antibiotics is acceptable for urinary tract infections because the antimicrobial susceptibility tests can underestimate the true activity of the drugs *in vivo*.

If the animal is an intact male, infection of the prostate gland is possible. Drug penetration into the prostate is limited because of a barrier between prostatic glandular cells and the serum or plasma.[11] Drugs that are poorly lipophilic at the pH of plasma (e.g., penicillins, cephalosporins, and aminoglycosides) do not diffuse well into prostate. Drugs that are lipophilic at the pH of plasma, such as macrolides (e.g., erythromycin), lincosamides (e.g., clindamycin), trimethoprim, or fluoroquinolones diffuse more easily into the prostate and can achieve concentrations in the prostate that exceed plasma concentrations. However, the macrolides and clindamycin usually do not have the gram-negative spectrum needed for a prostate infection. Therefore the most effective drugs for prostatic infections are the fluoroquinolones, and trimethoprim (usually administered as the combination of trimethoprim-sulfonamide). Chloramphenicol and tetracycline concentrations in prostate fluid of dogs are low after systemic administration.

135.5.3 Respiratory Tract Infections

Treatment of infections in the respiratory tract is challenging because these usually occur in small animals that are compromised by another primary problem, such as megaesophagus or immunosuppression. Antibiotics distribute into the parenchyma of lung tissue and achieve therapeutic drug concentrations in most cases because there are no barriers to diffusion as long as there are not consolidated lung lobes. Drugs administered to animals with pneumonia will achieve concentrations in the extracellular fluid of the lungs that are equal to, or exceed, plasma concentrations. However, the bronchial secretions present a barrier owing to the blood-bronchus barrier, and non-fenestrated capillaries of the alveoli. In these cases there may be insufficient drug concentrations in the epithelial lining fluid of the respiratory tract to treat infections associated with bronchitis.[12]

Drugs with poor lipid solubility such as penicillins and aminoglycosides produce low concentrations in bronchial secretions after systemic administration, but this barrier may be diminished when it is inflamed. Drugs that are able to achieve effective concentrations in bronchial secretions are macrolide antibiotics, tetracyclines (but not necessarily doxycycline), chloramphenicol, and fluoroquinolones. (However, the availability of chloramphenicol has diminished recently.)

When the infection is in the chest cavity (e.g., pyothorax) drug diffusion into the pleural cavity is not compromised. However, when fluid is present, or the condition has caused pus and fibrin to accumulate, this may compromise diffusion of antibiotic concentrations in the chest cavity high enough to achieve a cure. In these cases, effective drainage or surgical intervention is necessary to assist drug penetration.

The bacteria causing respiratory infections in small animals can cover the full spectrum of gram-positive, gram-negative, and anaerobes and may include *Bordetella bronchiseptica, Streptococcus zooepidemicus, E. coli, P. aeruginosa, K. pneumoniae, Staphylococcus* spp., alpha-and beta-streptococci, and *Pasteurella multocida*. A culture and sensitivity test obtained from a bronchoalveolar lavage (BAL) or transtracheal wash (TTW) is usually used for drug selection. However, the results of a TTW or BAL may not always represent the bacterial pathogen causing disease deeper in the lung, nor are cultures from nasal secretions likely to represent the cause of an infection deeper in the airways.

In the case where a gram-positive cocci is identified, or a gram-positive anaerobe, a penicillin, cephalosporin, or a penicillin-β-lactamase inhibitor combination (e.g., amoxicillin-clavulanate or ampicillin-sulbactam), is a good choice. When the organism is a gram-negative bacilli, a fluoroquinolone, aminoglcoside (e.g., amikacin, tobramycin, or gentamicin), or an extended-spectrum cephalosporin (e.g., cefoxitin, cefotaxime) are needed. Combinations of these drugs are rational in cases of mixed infections.

The role of *Mycoplasma* spp. in respiratory infections has been a source of debate. Although *Mycoplasma* spp. can be isolated from a high percentage of animals with respiratory signs, it is unclear whether or not this organism plays a role in the disease. It also is possible that the *Mycoplasma* spp. are simply inducing inflammation that has allowed other organisms to colonize the respiratory tract. Most *Mycoplasma*-positive dogs have co-infection with other organisms, and selection of drugs active against *Mycoplasma* is usually not an important factor in achieving a cure.

Bordetella bronchiseptica presents a special case. *Bordetella* spp. are a gram-positive aerobic coccobacilli. Among its important virulence factors is the ability to adhere to the bronchial epithelium (ciliated epithelial cells) and produce exotoxins that inhibit neutrophil migration to the infection site. Infections are often mild and self-limiting that require no specific antibiotic treatment. But in cases where antibiotics are indicated, one should select a drug that achieves concentrations in bronchial secretions, such as: tetracyclines, chloramphenicol, or macrolides (e.g., erythromycin, azithromycin). Aminoglycosides, cephalosporins, and penicillins may not achieve drug concentrations at the infection site and quinolones are not consistently active against this organism. Another treatment route that is considered is aerosolization of antibiotics (e.g., tobramycin).

502

503

135.5.4 Treatment of Infections in Bones and Joints

Staphylococci, *E. coli, Pseudomonas, Proteus,* and anaerobes have been causes of joint and bone infections in small animals. Often these may be mixed infections. Staphylococci can be particularly troublesome because they adhere to bone by expression of receptors for components of bone matrix. It also may be internalized by osteoblasts and survive intracellular. Infections in bone, especially those associated with surgical sites that

contain metal implants, are difficulty to treat because of the presence of a biofilm that can render bacteria resistant to antibiotics.[13]

Aggressive treatment is necessary because the consequences of treatment failure is often loss of a limb or long-term morbidity. Drug selection should be made on the basis of a reliable susceptibility test taken from a culture deep within the wound. Drug safety also is an important consideration since treatment is required for a long duration, usually a minimum of 6 weeks. Bone and joints do not present a barrier for drug diffusion; therefore one drug group is not preferred over another because of superiority of better penetration. However, the presence of pus, necrotic tissue, devitalized bone, or foreign body may delay antibiotic diffusion. Surgery to remove or reduce this material is recommended.

β-lactam antibiotics active against staphylococci can be administered orally for long periods. These first-line drugs include first-generation cephalosporins (e.g., cefadroxil, cephalexin), and amoxicillin-clavulanate. Other drugs effective for small animals are the fluoroquinolones, and clindamycin. Bacterial infections caused by *Pseudomonas* spp., *E. coli,* or *Enterobacter* spp. may be resistant to the drugs listed above and a susceptibility test is needed to accurately select the most appropriate drug. In some instances, aggressive treatment with injectable drugs may be necessary.

135.5.5 Treatment of Nonspecific Fever

Often the only sign of a potential infection is fever. If there also is evidence that the patient is immunosuppressed, antibiotic therapy is justified. Evidence of immunosuppression may include documented neutropenia, corticosteroid administration, Cushing's disease, or anticancer treatment. In patients treated for cancer, granulocyte counts less than 1000 cells/μL accompanied by fever should immediately warrant antibiotic administration. Blood cultures are recommended but may be unrewarding. Since results of blood culture may not be available for 48 to 72 hours, empirical antibiotic treatment should be instituted.

Select a drug protocol that gives maximum coverage with minimal risk of adverse effect. For patients that can be treated with oral drugs, a combination of a fluoroquinolone (e.g., enrofloxacin, difloxacin, marbofloxacin, or orbifloxacin) plus a potentiated amoxicillin (e.g., Clavamox) or an oral cephalosporin (e.g., cephalexin or cefadroxil) is a rational combination with a high safety index. If the patient is more critically ill, or if the infection becomes more life-threatening, injectable drugs should be considered. In these cases, the combination of an aminoglycoside (gentamicin or amikacin) plus a cephalosporin or potentiated ampicillin (e.g., Unasyn) is a rational combination. Alternatively, injectable enrofloxacin plus a cephalosporin (e.g., cefazolin), or potentiated ampicillin (e.g., ampicillin-sulbactam combination: unasyn) covers the spectrum of bacteria that may be causing the problem. If the organism has been refractory to therapy and resistance is possible due to infection caused by *E. coli, Klebsiella* spp., or another gram-negative bacilli. In these situations, the administration of drugs with greatest activity should be considered, such as cefotaxime, amikacin, or possibly a carbapenem (e.g., imipenem-cilastatin, or meropenem).

136 CHAPTER • 136 Glucocorticoid Therapy

Leah A. Cohn

Glucocorticoid agents are among the most commonly used veterinary drugs. They exert myriad effects on nearly every tissue in the body and result in desired and undesired actions. These effects vary with potency and preparation of the glucocorticoid product, dose and route of administration, duration of glucocorticoid exposure, and individual patient factors. Most often, the desired action of therapeutically administered glucocorticoids is suppression of inflammation or of a damaging immunologic response. Other properties of glucocorticoids are exploited for the treatment of hormonal deficiency states, neoplasia, and shock, among other miscellaneous uses.

Unfortunately, even for disease states in which glucocorticoid therapy is proven to be beneficial, there is little scientific evidence of what constitutes an optimum treatment protocol. Instead, veterinarians rely largely on anecdote and experience to design glucocorticoid treatment regimens. Because effects vary with dose and potency, the veterinarian must be familiar with the equivalent dose range of various drug preparations required to produce physiologic, anti-inflammatory, immunosuppressive, or other effects. As a general rule, glucocorticoids should be used "to effect" rather than at an arbitrary dose and therefore minimize exposure and adverse effects.

136.1 PHYSIOLOGY OF GLUCOCORTICOIDS

Glucocorticoid drug preparations are derivatives of the endogenously produced adrenal hormone cortisol (hydrocortisone). Most glucocorticoid actions result from altered cellular gene transcription.[1] Glucocorticoids move passively into cells and then bind intracytoplasmic receptors; receptor numbers vary with tissue and cell type. Bound receptors translocate to the nucleus, where they modify gene transcription. Proteins are either up-or down-regulated by the actions of glucocorticoids, which leads to specific cellular actions. Together, these actions affect the function of nearly every tissue type and result in a tremendous variety of effects (Box 136-1). Metabolic, anti-inflammatory, and immunosuppressive effects of glucocorticoids are particularly relevant to their therapeutic use.[2] Metabolic effects are primarily catabolic and include insulin antagonism, increased glycogen formation, and increased gluconeogenesis. Glucocorticoids inhibit liberation of arachidonic acid to diminish production of eicosanoid proinflammatory mediators, and they increase production of anti-inflammatory proteins.[3]

Many anti-inflammatory effects of glucocorticoids overlap with immunosuppressive effects. The glucocorticoid stress leukogram (mature neutrophilia, lymphopenia and eosinopenia, and variable monocytosis) results from altered membrane expression of cellular adhesion molecules. The most pronounced immunologic effects of glucocorticoids are diminished mononuclear phagocytic function and altered cytokine production.[3] Although glucocorticoids affect cell-mediated immunity directly and profoundly, the effect on humoral immunity is largely indirect and not as pronounced.[3] Although dog and cat lymphocytes are resistant to glucocorticoid-induced lysis, neoplastic and activated lymphocytes are susceptible to glucocorticoid-induced apoptosis.[3]

136.1.1 Box • 136-1 Selected Physiologic Effects of Glucocorticoids

136.1.1.1 Metabolic Effects

Increase gluconeogenesis

Increase protein catabolism

Antagonize insulin

Mobilize free fatty acids

Redistribute adipose tissue

136.1.1.2 Dermal Effects

Thinning or atrophic skin

Atrophic hair follicles

136.1.1.3 Cardiovascular Effects

Optimize catecholamine receptor numbers

Positive inotropic effects

Vasoconstriction

136.1.1.4 Gastrointestinal and Hepatic Effects

Induce alkaline phosphatase enzyme (dogs only)

Decrease calcium and iron absorption

Promote hepatic fat and glycogen deposition

Alter mucin structure

Increase secretion of digestive hormones

136.1.1.5 Renal Effects

Increase glomerular filtration rate

Inhibit renal tubules response to antidiuretic hormone

Promote water, sodium, and chloride retention

Promote potassium and calcium excretion

136.1.1.6 Neurologic and Muscular Effects

Euphoria or behavioral change

Increase numbers or sensitivity of adrenergic receptors

Muscular atrophy

Muscular weakness

136.1.1.7 Endocrine Effects

Decreased ACTH production

Suppressed thyroid stimulating hormone and T3/T4 concentrations

136.1.1.8 Hematopoietic Effects

Increase circulating mature neutrophils

Decrease circulating lymphocytes, lymphocyte sequestration, lymphoid tissue involution

Apoptosis of activated and neoplastic lymphocytes

Decrease circulating eosinophils

Increase circulating monocytes

Increase circulating red blood cells

Increase circulating platelets

136.1.1.9 Inflammatory and Immunologic Effects

Decreased eicosanoid (prostaglandin and leukotriene) formation

Inhibit mononuclear phagocytosis and chemotaxis

Decrease or increase cytokine production

Depress cell-mediated immunity

Diminish humoral immunity (secondary effect)

136.1.1.10 Miscellaneous Effects

Stimulate appetite

Inhibit fibroblast proliferation and collagen synthesis

Accelerate bone reabsorption

Stabilize lysosomal membranes

Antioxidant

The release of endogenous glucocorticoids is controlled by an endocrine-feedback axis consisting of the hypothalamus, the pituitary gland, and the adrenal gland (HPA axis).[2] The hypothalamus produces

corticotropin-releasing hormone (CRH), which stimulates production of adrenocorticotropic hormone (ACTH) from the anterior pituitary gland. In turn, ACTH causes production and release of cortisol from the zona fasciculata and zona reticularis of the adrenal cortex. Cortisol then inhibits release of CRH and ACTH and dampens further glucocorticoid production. Pharmacologic derivatives of cortisol exert a similar negative feedback, but suppression varies with glucocorticoid potency.

136.2 PHARMACOLOGY OF GLUCOCORTICOIDS

Numerous modifications of the 17-carbon atom steroid nucleus have been developed to enhance or diminish particular glucocorticoid drug properties (e.g., mineralocorticoid or glucocorticoid potency, receptor binding strength).[4] Other modifications have been made through esterification of the glucocorticoid drug product to change solubility and duration of action.[4] Although affinity of the particular product varies, the majority of glucocorticoid in plasma is bound to proteins. Corticosteroid binding globulin (transcortin), and to a lesser extent other proteins including albumin, hold glucocorticoid unavailable for diffusion into the cell.[4] Only glucocorticoid in excess of this binding capacity enters the cell and exerts a biologic effect.

504
505

Modifications of the basic glucocorticoid hormones have resulted in the development of numerous drug products available for either systemic or topical administration. The potency of these products is expressed as it relates to cortisol (Table 136-1). Importantly, the same metabolic effect can be attained by any of these glucocorticoid products when administered in a metabolically active form at equipotent dosages. The biologic half-life of systemically administered glucocorticoids is disparate from the plasma half-life. Because the biologic effects are largely due to alterations in genetic regulation of protein production, biologic effects are delayed and prolonged in comparison with plasma drug concentration. Glucocorticoid drugs are often divided into three groups based on duration of HPA suppression. Short-acting glucocorticoids typically suppress the HPA less than 12 hours; long-acting glucocorticoids more than 48 hours; and intermediate-acting products fall somewhere between.[5]

Many glucocorticoid products are combined with esters that affect water solubility of the compound and therefore affect rate of absorption of injectable preparations.[4] Sodium phosphate, hemisuccinate, and sodium succinate esters are the most water soluble and allow for rapid absorption and action. The duration of action of these esterified compounds is equivalent to that of the base glucocorticoid. Acetate and diacetate esters are poorly water soluble, whereas pivalate, diproprionate, hexacetate, and acetonide are least soluble. Slow absorption from the site of injection prolongs the duration of action of any glucocorticoid base with which these esters are combined.[4,5] For example, although the biologic duration of methylprednisolone is 12 to 36 hours, the duration of the repositol formulation methylprednisolone acetate is 3 to 6 weeks.

Certain synthetic glucocorticoid compounds require conversion to an active metabolite.[6] An example is prednisone, which requires hepatic conversion to prednisolone for activity; prednisone would therefore not be suitable for topical application. The two drugs are used interchangeably via systemic administration, however, because hepatic conversion is rapid and nearly complete.

Table • 136-1 Comparison of Various Glucocorticoids

	RELATIVE ANTI-INFLAMMATORY POTENCY	EQUIVALENT PHARMACOLOGIC DOSE (mg)	RELATIVE MINERALO-CORTICOID POTENCY	PLASMA HALF-LIFE DOGS/PEOPLE (HOURS)	BIOLOGIC HALF-LIFE IN PEOPLE (HOURS)
Short-Acting Glucocorticoids					
Hydrocortisone	1	20	2	1/1.5	8–12
Cortisone	0.8	25	2	?/1.5	8–12
Intermediate-Acting Glucocorticoids					
Prednisone	4	5	1	?/1	12–36
Prednisolone	4	5	1	1–3/2–3	12–36
Methyl-prednisolone	5	4	0	1.5/3	12–36
Triamcinolone	5	4	0	?/4 or more	24–48
Long-Acting Glucocorticoids					
Dexamethasone	30	0.75	0	2/5 or more	35–54
Betamethasone	30	0.6	0	?/5 or more	>48

An anecdotally supported belief by some veterinarians holds that a proportion of normal cats inadequately convert prednisone to prednisolone, so prednisolone is often preferred in this species. Cats have fewer, less sensitive, cellular glucocorticoid receptors than dogs.[7] Therefore cats often require twice the glucocorticoid dosage to achieve equivalent biologic effects, and side effects of glucocorticoid use in cats are less pronounced than those in dogs.

136.3 CLINICAL UTILITY OF GLUCOCORTICOIDS

Glucocorticoids are used to treat a variety of disease processes and often suppress the consequences of disease rather than curing disease. Evidence supporting these usages varies from irrefutable (e.g., hypoadrenocorticism) to unsubstantiated (e.g., septic shock). Even when good evidence exists to support the use of glucocorticoids in a particular disease process, there are few “right” or “wrong” treatment regimens.

Equipotent amounts of any metabolically active glucocorticoid exert similar effects, which means that a higher dose of a less potent glucocorticoid can achieve the same effect as a lower dose of a more potent product. Physiologic actions of glucocorticoids occur at a much lower dose of an equipotent glucocorticoid than do anti-inflammatory effects, which in turn occur at a lower dose than do immunosuppressive effects.[8] When choosing an initial treatment protocol, the veterinarian must begin by recognizing a goal of glucocorticoid therapy (physiologic replacement, suppression of inflammation, suppression of immunity, or some other action). Additional variables relate to the patient (e.g., species, concurrent disease), the disease process (e.g., chronic or acute, localized or systemic), and available glucocorticoid products (e.g., solubility, duration of action, route of administration). Ideally, when glucocorticoid therapy is required in only a localized area (e.g., ocular inflammation), treatment can be administered topically, thus minimizing effects of glucocorticoids on other tissues. Systemic therapy using parenteral or oral products is best suited to situations in which several body systems and/or tissues are targeted for therapy (e.g., anaphylaxis, systemic lupus erythematosus). Realistically, glucocorticoids are often administered systemically even when only a single tissue is targeted.

136.3.1 Physiologic Replacement Therapy

Hypoadrenocorticism is the failure of the adrenal gland to produce enough corticosteroid hormones. Commonly, both mineralocorticoid and glucocorticoid deficiency exists, but isolated glucocorticoid deficiency can occur. Administration of prednisone or methylprednisolone, which are detected along with endogenous cortisol during assay, should be avoided prior to completion of diagnostic ACTH stimulation testing. If a substantial delay in testing is unavoidable, dexamethasone may be administered (0.1 to 0.2 mg/kg) without altering diagnostic test results. Life-long hormonal replacement is the basis of therapy.[9]

Although some corticosteroid drugs possess glucocorticoid and mineralocorticoid activity, separate replacement of each is often required. The glucocorticoid of choice for replacement should be administered systemically at a physiologic dose and should have a biologic duration of approximately 24 hours. Predniso(lo)ne 0.2 to 0.3 mg/kg once daily meets these requirements. During times of stress (e.g., boarding, illness) the amount of glucocorticoid administered should be temporarily increased (typically doubled) to meet increased physiologic demands.[9]

136.3.2 Anti-Inflammatory Therapy

Glucocorticoids are used most often for their excellent anti-inflammatory properties. Prior to initiating glucocorticoid therapy, attempts should be made to identify and eliminate the underlying cause of inflammation. Frequently, an underlying cause either cannot be found or cannot be entirely eliminated. Anti-inflammatory therapy can be of benefit in such cases, and glucocorticoids are often the most effective such therapy.

It is particularly important to rule out infectious causes of inflammation, especially fungal infection, prior to beginning glucocorticoid therapy. Because inflammation is intimately tied to innate defense mechanisms, and because of the additional suppressive effects of glucocorticoids on specific immunity, these drugs are relatively contraindicated in infection. Glucocorticoids often lead to a temporary improvement in animals with inflammation secondary to infection, but failure to control infection can lead to worsening of disease or even death. Because glucocorticoids reduce fever, stimulate appetite, and can induce feelings of euphoria and suppress clinical evidence of inflammation, it can be difficult to detect worsened infection until it is too late. There are exceptions to every rule, and glucocorticoids are actually indicated for the treatment of some infectious diseases.[10] Typically, they are combined with antimicrobial therapy to reduce inflammatory (e.g., *Pseudomonas* otitis)[11] or immunologic (e.g., red cell destruction due to *Mycoplasma hemofelis*) consequences of infection.[12]

Specific treatment decisions regarding anti-inflammatory therapy with glucocorticoids are based on a number of factors, including desired rapidity of action and expected duration of therapy. Rarely, a rapid onset of action is required, such as when respiratory inflammation compromises the animal's ability to breathe; injectable phosphate or succinate preparations are most useful in these situations. In most cases, anti-inflammatory therapy will be required for days, weeks, or months. Intermediate acting steroid preparations allow dosage to be titrated to effect and thereby minimized for chronic administration. The most often used anti-inflammatory glucocorticoid is predniso(lo)ne at an initial dosage of 0.5 to 1.0 mg/kg/day for dogs or 1 to 2 mg/kg/day for cats. Because the biologic half-life is 24 to 36 hours, there is little obvious advantage to division of the daily dosage. Once initial inflammation is suppressed, steroid dose is reduced to the lowest necessary level. Treatment with repositol products (e.g., methylprednisolone acetate) is not advisable in dogs even when

long-term therapy is anticipated. Repositol therapy severely suppresses the HPA axis, prevents accurate dose titration or early drug withdrawal, and is associated with more pronounced side effects. Additionally, such therapy can interfere with accurate diagnostic testing (e.g., allergen skin testing, endocrine testing) for long periods of time.[13] There are limited indications for the use of repositol therapy in steroid-resistant cats. Repositol therapy may be used to treat feline eosinophilic granuloma or allergic and inflammatory skin conditions when the owners are unwilling or unable to administer oral medications, but iatrogenic hyperadrenocorticism and its consequences (i.e., insulin resistance) may result.[14]

Regional inhibition of inflammation can often be accomplished via local application of glucocorticoids. Glucocorticoid products are available in a variety of formulations designed specifically for local application, and injectable preparations can be used to achieve a local effect. Because the intended actions are local rather than systemic, the products should include only metabolically active glucocorticoids (e.g., prednisolone rather than prednisone). Although local application minimizes unwanted effects, absorption does occur and can lead to systemic effects and suppression of the HPA axis.[15,16]

The eyes, skin, respiratory and gastrointestinal tracts, and joints are the sites most often treated via local glucocorticoid application. Topical suspensions (e.g., 1.0% prednisolone acetate), solutions (e.g., 0.1% dexamethasone phosphate), or ointments (e.g., 0.05% dexamethasone phosphate) are indicated for inflammatory disease of external ocular structures or the anterior segment, such as non-infectious conjunctivitis or uveitis. Therapy is typically titrated to effect by adjusting frequency of application (every 1 to 8 hours). Contraindications to ocular glucocorticoid use include corneal ulceration or ocular infection. Ulcers can be exacerbated by glucocorticoids, and in the presence of infection stromal melting may occur.[17] Because of its frequent association with infection, feline conjunctivitis is a relative contraindication to ophthalmic glucocorticoid use.[18]

Dermatologic inflammation is often treated via systemic glucocorticoid administration, but topical products can augment or replace systemic glucocorticoids. Glucocorticoids should not be used to treat dermatologic disorders until serious attempts are made to diagnose the cause of dermatopathy. They should only be used after efforts are exerted to eliminate or control precipitating and predisposing factors. Even then, steroids should be used sparingly; topical therapy may spare excessive tissue exposure. Glucocorticoids in the form of 1% hydrocortisone (the metabolically active form of cortisone) are available in shampoos, conditioners, lotions, creams, ointments, and otic medications. These products are particularly useful in reduction of pruritus associated with atopy when used in conjunction with other therapies such as antihistamine medications. Stronger glucocorticoid preparations, including triamcinolone acetonide (e.g., Panalog®), betamethasone valerate (e.g., Gentocin Spray®, Otomax®) and fluocinolone acetonide (e.g., Synotic®), are effective in reducing erythema, swelling, and pruritus. However, systemic absorption makes these products inappropriate for extended daily use, particularly when dermal barriers are no longer intact.

Glucocorticoids are frequently used to treat chronic inflammation of the respiratory and gastrointestinal tracts. Methods of local application have been developed for use in people to minimize the adverse effects associated with long-term systemic administration. Metered dose inhalers (MDI), nasal sprays or drops, glucocorticoid retention enemas, rectal foams, and suppositories can be used in small animals. Although systemic steroid administration remains the mainstay of treatment for cats with reactive airway disease, bronchodilators and glucocorticoids (e.g., fluticasone propionate) can be applied to the airway lumen directly via MDI delivery.

Delivery systems for MDI use in cats can either be obtained commercially or made by simple modification of readily available, inexpensive equipment.[8] Although unproven, the method has met with good anecdotal success. Some dogs and cats with allergic or idiopathic rhinitis respond well to intranasal glucocorticoids; such

therapy should not be attempted until neoplastic and infectious diseases have been ruled out. Nasal sprays are available, but two drops of ophthalmic 1% prednisolone acetate instilled in each nostril two to three times daily can be used successfully. Topical therapy of gastrointestinal disease is limited to the mouth, rectum, and colon. Dogs with refractory colitis have been successfully treated with glucocorticoid suppositories and rectal foams, whereas successful intralesional injection of oral eosinophilic granuloma with glucocorticoids has been described in cats.[8,13]

Orthopedic pain and inflammation may be relieved by local injection of glucocorticoids, although such injections are never considered curative. Although injections can bring about a rapid return to function, they are also associated with potentially devastating complications (e.g., cartilage damage and impaired healing of osteochondral defects, accelerated osteoarthritis, and joint sepsis).[19,20] Intra-articular glucocorticoids injections are used less often in small animals than in either horses or people.[19,21] Perhaps the best use of local glucocorticoid therapy in small animal orthopedic medicine is in the treatment of bicipital tenosynovitis in dogs. Typically, 1 mg/kg of repositol methylprednisolone acetate is injected directly into the tendon and tendon sheath.[22] Injection is followed with several weeks' strict rest prior to slow return to activity.

136.3.3 Immunosuppressive Therapy

Suppression of damaging immunologic responses in dogs and cats is most often achieved by the administration of systemic glucocorticoids at a dosage higher than that required to suppress inflammation. The beneficial role of glucocorticoids in the treatment of autoimmune disease is well documented. Additionally, glucocorticoids are used to suppress harmful immunologic reactions associated with diseases like feline infectious peritonitis or rejection of transplanted organs.[23,24] Oral administration of intermediate-acting preparations is the most common choice for chronic immunosuppression. The initial dose of predniso(lo)ne required for immune suppression is usually 2 to 4 mg/kg/day for dogs or 2 to 8 mg/kg/day for cats. Despite predniso(lo)ne's biologic half-life of 24 to 36 hours, dividing this high dose and administering the drug twice daily may lessen GI irritation.

Some clinicians recommend initiating immunosuppressive therapy with dexamethasone rather than prednisone,[25] but evidence for an advantage of one drug over the other at equipotent dosages is lacking. Dexamethasone injection should be chosen when oral drug administration is difficult (e.g., due to vomiting or inability to swallow). Ideally, once disease is controlled, the use of glucocorticoids can be slowly tapered until it is discontinued altogether.

Immune-mediated disease refractory to glucocorticoids alone may be controlled by the addition of a different immunosuppressive agent (e.g., azathioprine). Such combination therapy may have a steroid sparing effect, which allows control of disease using a lower total glucocorticoid dose. This type of combination therapy is particularly useful in animals with unacceptable adverse effects from glucocorticoid therapy.

136.3.4 Anti-Neoplastic Therapy

Glucocorticoids have proven useful in the treatment of several neoplastic and paraneoplastic conditions. Benefits can be attributed to direct tumorcidal effects, anti-inflammatory and/or immunosuppressive properties, and to metabolic properties of glucocorticoids. Commonly, glucocorticoids are used in conjunction with other chemotherapeutic agents in the treatment of lymphoma.[26] Although glucocorticoids sometimes induce remission of lymphoma when used alone (predniso[lo]ne 2 mg/kg/day), rapid development of multi-drug resistance leads to brief remission and decreases the chance that other, more aggressive chemotherapy protocols

will be successful.[26] Because glucocorticoids induce apoptosis of neoplastic lymphocytes, the use of these drugs prior to diagnosis may interfere with the ability to cytologically or histopathologically confirm lymphoma. Other cancer types that may respond directly to glucocorticoids include multiple myeloma, certain leukemias, and mast cell tumors.[26–28]

Some paraneoplastic syndromes and some complica-tions from neoplasia may respond to glucocorticoid therapy even when glucocorticoids are not directly tumorcidal.[8] Glucocorticoids are antagonistic to insulin and are therefore used to increase plasma glucose concentrations in animals with insulinoma (predniso[lo]ne 0.5 mg/kg/day). Hypercalcemia resulting from lymphoma or a variety of other neoplastic conditions may respond to systemic glucocorticoid therapy as well (predniso[lo]one 1 to 2 mg/kg/day). In addition to direct effects on lymphoid neoplasia, they inhibit bone resorption, inhibit intestinal calcium absorption, and promote caluresis. Edema and inflammation associated with many types of neoplasia are frequently treated with systemic glucocorticoid therapy on either a short (e.g., during perioperative period surrounding tumor manipulation) or long-term basis (e.g., as palliative therapy for brain tumor).

136.3.5 High Dose, Short-Term Therapy

In certain disease processes, glucocorticoids are used for short periods (often a single dose) in dosages much higher than those required to initiate immunosuppressive therapy. At such dosages glucocorticoids exert actions in addition to those mediated by gene transcription; these actions are somewhat nebulous but include antioxidant properties, membrane stabilization, and hemodynamic effects. Examples of processes treated in this way include central nervous system trauma and various shock states.[29–31] Because a rapid onset of action is required, injectable succinate and phosphate esters are most appropriate. Animals with recent spinal cord injuries (<8 hours from time of insult) benefit from treatment with methylprednisolone sodium succinate (15 to 40 mg/kg IV), although a similar benefit has not been demonstrated for animals with brain injury.[29,32,33] Repeated boluses of 15 mg/kg may be administered 2 and 6 hours later, followed by either boluses of 7.5 mg/kg every 6 hours for 24 hours or by a 24 hour continuous rate infusion of 2.5 mg/kg/hr.

High-dose glucocorticoid treatment for shock has fallen repeatedly in and out of favor. Anaphylactic shock is the only type for which routine treatment still involves the administration of high-dose glucocorticoids.[34] Decades ago, high-dose glucocorticoids were used to treat hemorrhagic shock because of their ability to increase blood pressure. Steroids have fallen out of favor for this use, and treatment should focus on volume, colloid, and hemoglobin replacement. The role of glucocorticoid therapy in septic shock is more controversial. Experimental literature of the 1970s seemed to support claims that high doses of short-acting glucocorticoids (30 mg/kg methylprednisolone) decreased morbidity from septic shock. However, clinical trials in people failed to support these claims, and high-dose steroid therapy in sepsis was discouraged.[35] Recently, glucocorticoids have regained favor in the treatment of sepsis and septic shock, but at much lower dosages designed to counter occult adrenal insufficiency.[36] Thus far, occult adrenal insufficiency has not been documented in critically ill dogs,[37] which leaves the role of low-dose steroids for septic animals in doubt.

Many veterinarians utilize short-term high dose glucocorticoid therapy for treatment of conditions in which massive cytokine release is anticipated (e.g., gastric-dilatation volvulus, snake bite envenomation). A beneficial role for glucocorticoids in most such situations has been neither confirmed nor denied. Serious complications from intensive short-term glucocorticoid treatment are rare, but they do occur.[38] Therefore it is difficult to recommend high-dose glucocorticoids therapy in the absence of proven benefit for these types of conditions.

507 508

136.4 ADVERSE EFFECTS OF GLUCOCORTICOIDS

Adverse reactions associated with glucocorticoids are numerous and range from the merely bothersome to the life threatening (Box 136-2). Conditions exacerbated by glucocorticoid effects (e.g., infection, diabetes mellitus, pancreatitis) are relative contraindications to their use. Generally speaking, the more potent the product, higher the dosage, and more prolonged the administration, the more serious are the adverse effects. The most common side effects of glucocorticoid use are polyuria, polydipsia, and polyphagia. Iatrogenic hyper-adrenocorticism, distinguishable from pituitary or adrenal dependent hyperadrenocorticism only through clinical history and suppression of response to exogenous ACTH, can occur during prolonged corticosteroid administration.[39] Rapid withdrawal of exogenous glucocorticoids in an animal with suppression of the HPA axis can leave the adrenal gland unable to produce requisite levels of glucocorticoids, creating a state of adrenocortical insufficiency that can have life-threatening consequences. More commonly, rapid cessation of chronic (>2 weeks) therapy results in a constellation of clinical signs including depression, decreased appetite, and vomiting.

136.4.1 Box • 136-2 Adverse Effects of Glucocorticoid Administration

Abortion

Alopecia

Calcinosis cutis

Colonic perforation

Comedones

Delayed wound healing

Diabetes mellitus

Gastrointestinal ulceration

Growth suppression

Hypercoagulable state

Hyperlipidemia

Iatrogenic hyperadrenocorticism

Immunosuppression (secondary infection, worsened infection, recrudescence of latent infection)

Insomnia, agitation, behavioral changes

Insulin resistance

Ligament and tendon rupture

Muscle atrophy

Muscle wasting

Myotonia/myopathy

Osteoporosis

Panting

Polyphagia

Polyuria/polydipsia

Proteinuria

Psychosis/behavioral change

Seizure threshold lowered

Skin thinning

Vacuolar hepatopathy

Glucocorticoid administration can impact therapy with other pharmaceutical agents. For example, animals receiving immunosuppressive dosages of glucocorticoids should not be given modified live vaccines due to the risk of vaccine-induced disease.[40] Certain pharmaceuticals alter metabolism or clearance of the glucocorticoids,

which results in either increased or decreased biologic glucocorticoid effects at a given steroid dose. Additionally, glucocorticoids can impact the effectiveness or toxicity of co-administered pharmaceuticals.[41]

136.5 GLUCOCORTICOID REDUCTION PROTOCOLS

Ideally, glucocorticoids should be used at the lowest dose possible to achieve the desired effect. When administered for more than 2 weeks, the dosage should be reduced slowly. This principle fits nicely with the ideal of adjusting the glucocorticoid dose "to effect," particularly in those cases requiring prolonged therapy (e.g., autoimmune disease).

Once clinical evidence suggests that the condition being addressed is controlled (e.g., red cell count normalized when treating immune mediated hemolytic anemia [IMHA], diarrhea resolved when treating inflammatory bowel disease), the dosage of glucocorticoids should be tapered. There is no single ideal way to conduct this tapering, but certain principles apply. First, the clinical condition should be monitored closely. Worsening soon after a dose reduction suggests that the taper is too rapid. Second, the severity of the condition holds implications as to the rapidity of the taper. Glucocorticoids used to treat life-threatening disease (e.g., IMHA) should be tapered more slowly than glucocorticoids used to treat other conditions. Third, consolidated dosing with prolonged dosing intervals might spare HPA suppression while maintaining much of the desirable biologic drug effect. For example, if administering 5 mg prednisone twice daily, it may be better to first switch to 10 mg once a day rather than simply decreasing the twice daily dose. The daily dose can then be decreased incrementally. Dose interval is then changed to an every-other-day (EOD) basis, usually when the daily dose nears a minimal anti-inflammatory range (0.5 mg/kg for dogs). Often, veterinarians choose to increase to dose given on the treatment day so that the total 2-day dose remains unchanged or only slightly decreased initially. Eventually, the glucocorticoid dose is lowered until it is discontinued altogether. Theoretically, EOD (or even every third day) dosing allows the HPA axis to recover from suppression during the "off steroid" day.[42,43] This type of EOD dosing scheme depends on the biologic duration of the steroid preparation and is thus only serviceable using intermediate acting glucocorticoids.

CHAPTER • 137 Over-the-Counter Human Medications

Etienne Côté

Using human nonprescription (over-the-counter, or OTC) drugs in veterinary medical therapy is an attractive option because these drugs usually are inexpensive and widely available. Veterinarians deal with OTC drugs either when they advocate their use for medical treatment or when they manage OTC drug intoxications.

A dizzying variety of brand names and products exists on the OTC pharmaceuticals market. Products with similar names often have very different components. Therefore the veterinarian needs to specify the active ingredients of the drug in question to avoid confusion. For example, many products containing acetylsalicylic acid (ASA) can safely be used for treating dogs and cats, yet varieties of these same products are available in nearly identical packaging and are labeled “aspirin-free,” “pain-relief,” “cold,” “flu,” or “sinus.” These versions often contain acetaminophen as the active ingredient instead of ASA and therefore have a completely different, and potentially adverse, pharmacologic profile.

A brand name alone (e.g., Anacin, Benadryl) often is inadequate and could be disastrously misleading. Manufacturers may change the contents of a product without changing the brand name. For example, the active ingredient in Kaopectate was formerly kaolin-pectin; now, the active ingredient is either attapulgite or bismuth subsalicylate, but the name of the product remains the same. When the veterinarian advocates the use of a product, confusion can be minimized by giving the client the names of the desired active ingredients and the name of active ingredients to avoid, in writing, and urging the client to seek pharmacist confirmation at the time of purchase (Box 137-1).

Human drugs approved for OTC sale in the United States must be proved to be safe and efficacious in humans, but not in ill dogs or cats. The absorption characteristics of OTC human preparations, particularly time-release or entericcoated formulations, are designed for the human gastrointestinal (GI) tract but not for that of dogs or cats. Clinical trials assessing the effectiveness of any human OTC-formulated drug against placebo in the veterinary setting remain rare. Therefore when a prescription veterinary drug is available, it may often be safer and more reliable to prescribe it rather than to advocate a human OTC equivalent.

137.1

Box • 137-1 Equivalence of Units Commonly Used in Over-the-Counter Human Medications

1 teaspoon (tsp) = 5 ml

1 tablespoon (tbsp) = 15 ml

1 fluid ounce (oz) = 28 ml

1 cup = 237 ml

1 grain = 65 mg

1 pound (lb) = 0.454 kg

None of the drugs described in this chapter has Food and Drug Administration approval for non-prescription use in dogs or cats in the United States. Advocating the use of these drugs in an extralabel manner signifies that the veterinarian and client understand the risk inherent in using medications not specifically designed for use in animals.

137.2 ANALGESICS

Aspirin, plain (e.g., Norwich, St. Joseph, Bayer, Anacin, ASA) or buffered (e.g., Bufferin, Ascriptin, Ecotrin), has traditionally been a common treatment for musculoskeletal pain in dogs and cats. The widespread availability of prescription anti-inflammatory drugs that cause fewer adverse GI effects (e.g., carprofen, etodolac, meloxicam) has made aspirin a second choice for therapy. A recommended therapeutic dose of aspirin in dogs is 5 to 12 mg/lb (10 to 25 mg/kg) by mouth two to three times a day, and dogs may require 10 to 39 mg/lb (23 to 86 mg/kg) twice a day to control signs of osteoarthritis. Substantial overlap between therapeutic and toxic doses exists; in dogs, doses of 12 mg/lb (25 mg/kg) by mouth three times a day for 14 days systematically produced adverse GI effects, and doses of 45 to 50 mg/lb (100 to 110 mg/kg) once a day for 1 to 4 weeks were lethal. Concurrent treatment with misoprostol or omeprazole can reduce GI toxicity, but treatment with the H_2-receptor blocking drug cimetidine does not.

Parenteral administration of the salicylates also produces GI toxicity; therefore administering aspirin in pulverized form and/or with a full meal may reduce topical irritation in the stomach, but not all adverse GI effects can be eliminated this way. One regular aspirin tablet, plain or buffered, typically contains 325 mg ASA; “baby” or “low-dose” tablets, 81 mg; and “extra strength” tablets, 500 mg.

Aspirin is indicated for anticoagulation in dogs and cats at doses much lower (dogs: 0.22 mg/lb [0.5 mg/kg] orally every 12 hours; cats: 81 mg/*cat* orally every 72 hours) than the anti-inflammatory dose. Few adverse GI effects can be expected at these doses, but efficacy in animals in a hypercoagulable state, particularly cats with heart disease that are susceptible to arterial thromboembolism, is questionable.

Acetaminophen (Excedrin, Feverall, Liquiprin, Midol, Panadol, Pamprin, Percogesic, Tempra, Tylenol, Bromo-Selzer, paracetamol, and many others, including most “aspirin-free” formulations) is an analgesic drug sometimes used in dogs (7 to 13 mg/lb [15 to 28 mg/kg] by mouth every 8 hours for up to 4 days). It is strictly contraindicated in cats because it induces methemoglobinemia and hemolytic anemia. Hematologic and hepatic adverse effects occur in dogs ingesting large doses (usually >45 mg/lb [>100 mg/kg], but as little as 9 mg/lb [20 mg/kg] in one case). Acetylcysteine (65 mg/lb [140 mg/kg] by mouth or slowly intravenously once, then 32 mg/lb [70 mg/kg] by mouth or slowly intravenously every 4 hours for three to seven treatments) is an antidote.

509

510

Other OTC nonsteroidal anti-inflammatory drugs are not currently recommended for veterinary use. Naproxen (e.g., Aleve, Naprosyn) and ibuprofen (e.g., Advil, Motrin, Nuprin) are associated with severe GI ulcerations and perforations in dogs. Ketoprofen (e.g., Actron, Orudis) is approved for use in horses as an injectable, Ketofen, and may eventually be approved for use in dogs and cats in the United States given its common use in small animal medicine in other countries. The current OTC human formulation, like other enteric-coated preparations, may have variable absorption characteristics in small animals.

137.3 ANTIDIARRHEALS

Such adsorbents as attapulgite (e.g., Kaopectate, Donnagel) are considered generally harmless but of questionable clinical efficacy. Bismuth subsalicylate (e.g., Pepto-Bismol, 8.7 mg salicylate/ml; Pepto-Bismol Maximum Strength, 15.7 mg salicylate/ml; Pepto-Bismol Caplets, 102 mg salicylate/caplet) has been shown to have a beneficial effect on the morbidity of acute diarrhea in humans. The liquid is given at a dose of 0.125 ml/lb (0.25 ml/kg, or approximately half of a 5 ml teaspoon for a 25 lb [11 kg] patient) by mouth every 4 to 6 hours in dogs and cats. Doses of up to 0.9 ml/lb (2 ml/kg) every 6 to 8 hours has been advocated for dogs only. Cats reportedly are more sensitive to salicylates than are dogs and probably should not receive frequent or high doses of bismuth subsalicylate because some of the salicylate is absorbed systemically.

Loperamide (e.g., Imodium A-D) is an effective opiate antidiarrheal medication. The recommended dose for dogs, 0.04 mg/lb (0.08 mg/kg) by mouth three to four times a day, may be difficult to achieve in smaller animals receiving the tablet form (2 mg loperamide/tablet). The oral liquid preparation (0.2 mg loperamide/ml) may allow a more accurate dosage in smaller patients (e.g., half of a 5-ml teaspoon for a 14 lb [6 kg] dog). Intoxication, manifesting with central nervous system (CNS) signs and vomiting, has been reported in dogs (especially collies) and cats. Naloxone (0.001 to 0.01 mg/lb [0.002–0.02 mg/kg] intravenously or intramuscularly) is an antidote.

137.4 ANTIEMETICS

The efficacy of OTC human antiemetics in small animal medicine remains unproved. Such drugs as dimenhydrinate (e.g., Gravol, Dramamine [50 mg/tablet]; dose: 2 to 4 mg/lb [4 to 8 mg/kg] by mouth up to every 8 hours), meclizine (e.g., Bonine, Dramamine II; dose: 0.6 mg/lb (1.25 mg/kg) by mouth once daily; maximum single dose: 25 mg), and cyclizine (e.g., Marezine) are sometimes given for the short-term prophylaxis of motion sickness in dogs and cats. Adverse effects appear to be uncommon, but CNS depression and lethargy have been reported anecdotally in dogs receiving 4 to 9 mg/lb [10 to 20 mg/kg] dimenhydrinate, and similar, mild signs have occurred with dogs that ingest meclizine 2.2 to 4.5 mg/lb (5 to 10 mg/kg).

137.5 CHRONIC RENAL FAILURE DRUGS

Such phosphate binders as aluminum hydroxide (e.g., Amphojel, 64 mg $Al(OH)_3$/ml; AlternaGEL, 120 mg $Al(OH)_3$/ml) are advocated for use in the treatment of hyperphosphatemia at an initial dose of 4.5 to 14 mg/lb (10 to 30 mg/kg) by mouth every 8 to 12 hours. Exact titration of the dose depends on effect (subsequent serum phosphorus levels). Constipation and loss of appetite are possible side effects. Other phosphate binders include calcium carbonate (e.g., Titralac, Tums [500 mg $CaCO_3$/tablet]; dose: 4.5 to 14 mg/lb [10 to 30 mg/kg] by mouth every 8 to 12 hours and adjusted based on degree of control of phosphorus levels), although less effective phosphate binding and hypercalcemia are possible drawbacks. The use of magnesium-containing phosphate binders (e.g., Maalox, Mylanta) is discouraged because of the commonly impaired ability to excrete magnesium in cases of renal failure, potentially leading to hypermagnesemia.

137.6 COUGH SYRUPS

Most OTC cough syrups contain one or more of the following five active ingredients: acetaminophen, chlorpheniramine, pseudoephedrine, guaifenesin, and dextromethorphan. Acetaminophen and pseudoephedrine are described elsewhere in this chapter. Guaifenesin is considered to be of minimal therapeutic value in the treatment of coughs; it has been thought to attenuate the cough reflex and to make respiratory secretions thinner, but clinical

trials have shown that it does neither. Antihistamines are considered minimally useful in the treatment of nonallergic causes of cough. Of these five active ingredients, dextromethorphan has been used successfully (though empirically) in the treatment of coughing dogs and cats at a dose of 0.22 to 0.9 mg/lb (0.5 to 2 mg/kg) by mouth every 6 to 8 hours. Although seemingly less effective than opioid antitussives, it is an effective cough suppressant and therefore is contraindicated when cough is beneficial, such as in the expectoration of pus in cases of pneumonia. Most cough syrups contain multiple active ingredients, and currently only a few, such as Vicks Formula 44 (not 44D, 44E, or 44M) and Robitussin Maximum Strength Cough contain only dextromethorphan (2 mg/ml and 3 mg/ml, respectively). Unwanted and potentially dangerous active ingredients are present in many preparations. For instance, NyQuil liquid contains dextromethorphan as a cough suppressant, but it also contains pseudoephedrine and more than 150 mg acetaminophen/5 ml teaspoon.

137.7 DERMATOLOGIC DRUGS

Several antihistamines are used in veterinary dermatology. Chlorpheniramine (e.g., Chlor-Trimeton; dose: 2 mg/*cat* by mouth every 12 hours; 2 to 8 mg/*dog* by mouth every 12 hours, not to exceed 0.22 mg/lb [0.5 mg/kg] every 12 hours), effectively controls 70% of seasonally pruritic cats and is of some value for the same problem in dogs. Clemastine fumarate (e.g., Tavist Allergy; dose: 0.022 to 0.045 mg/lb [0.05 to 0.1 mg/kg] by mouth every 12 hours) and diphenhydramine (e.g., Benadryl Allergy; dose: 1 to 2 mg/lb [2 to 4 mg/kg] by mouth every 8 hours) also control pruritus of allergic origin in some dogs.

Such topical antibacterials as bacitracin (e.g., Bacitracin Plus) and triple antibiotic combinations (e.g., Neosporin) are probably minimally effective but also minimally harmful. Such antifungals as clotrimazole (e.g., Lotrimin, Cruex) and miconazole (e.g., Micatin) are effective against several types of fungi, including *Malassezia* yeasts, dermatophytes, and saprophytes such as *Aspergillus* spp. The reader is referred to additional sources for exact protocols for the use of these drugs.

Zinc oxide creams (e.g., Desitin) frequently are applied to burned or irritated skin. The usefulness of zinc oxide in treating such conditions, and as a sunscreen, must be weighed against the potential for toxicity, which can manifest as vomiting and lethargy after animals lick the product off the skin.

510

511

Benzocaine is present in some dermatologic “soothing” preparations. It can cause hemolytic anemia in cats and dogs that ingest it. In these species, such preparations should be used cautiously if at all.

137.8 EMETICS

For those situations in which emesis is to be induced, oral administration of syrup of ipecac is effective and safe (2 to 6 ml by mouth). Only one additional dose is recommended if vomiting has not occurred within 15 minutes. Orally administered 3% hydrogen peroxide (dose: 0.11–0.22 ml/lb [0.25–0.5 ml/kg] by mouth; the dose can be repeated once after 5 to 15 minutes if vomiting has not occurred) also effectively induces emesis in many dogs and cats. Both of these products are widely available as generics. Large doses of table salt, although sometimes emetic, are not recommended because of the potentially serious consequences of hypernatremia if no vomiting occurs.

137.9 GASTRIC ACID–REDUCING DRUGS

The phosphate binders described earlier are also antacids. They are rarely used in canine and feline medicine because of the frequent dosing needed to maintain a high gastric pH. The H_2-receptor blocking drugs cimetidine (e.g., Tagamet HB 200; dose: 4.5 mg/lb [10 mg/kg] by mouth every 8 hours), ranitidine (e.g., Zantac; dose: 0.9 mg/lb [2 mg/kg] by mouth every 8 to 12 hours), famotidine (e.g., Pepcid AC; dose: 0.22 mg/lb [0.5 mg/kg] by

mouth every 12 to 24 hours), and nizatidine (e.g., Axid AR; dose: 1.1 to 2.2 mg/lb [2.5 to 5 mg/kg] by mouth every 24 hours) all decrease gastric acid secretion. Some (ranitidine, nizatidine) also have GI prokinetic activity. Famotidine and nizatidine do not affect hepatic p450 enzymes. The H_2-blockers have a wide margin of safety; for example, no deaths were recorded in dogs acutely given famotidine 900 mg/lb (2000 mg/kg) by mouth or nizatidine 360 mg/lb (800 mg/kg) by mouth, nor were there overt adverse effects in dogs given cimetidine 65 mg/lb (144 mg/kg) by mouth once daily for 7 years.

137.10 LAXATIVES AND ENEMAS

A variety of OTC preparations is available to effectively manage constipation. Such stimulant laxatives as bisacodyl (e.g., Dulcolax, Correctol, Ex-Lax Ultra; dose: 5 mg/*cat* by mouth once daily; 5 to 20 mg/*dog* by mouth once daily) increase myenteric nervous activity and peristalsis. They are advocated for short-term use only. Emollient laxatives (docusate [Colace, Surfak]; dose: 1 mg/lb [2 mg/kg] by mouth once daily in dogs; 25 mg/*cat* by mouth once daily) soften the stool and are said to be more effective in acute rather than chronic constipation. Hard capsule formulations make the dosage of this type of laxative challenging in small patients. Constipation prevention may be achieved using such soluble fiber products as psyllium mucilloid (e.g., Metamucil; dose: 1 tsp/11 to 22 lbs [5 to 10 kg] body weight, added to the food), with the exact dose titrated to result in soft, formed feces. Newer laxatives containing anthraquinone derivatives like senna have yet to be used in a widespread fashion in veterinary medicine and some aspects of their effects remain controversial in human gastroenterology.

Phosphate enemas (e.g., Fleet) are contraindicated in cats, and possibly small dogs, because of the severe hyperphosphatemia they induce. Instead, pediatric emollient enemas (e.g., docusate sodium) have been used successfully and safely.

137.11 OPHTHALMIC DRUGS

Irrigating solutions (e.g., Dacriose, Collyrium for Fresh Eyes) are used for cleaning debris and pus from the eyes on a short-to long-term basis. Artificial tears (e.g., Adsorbotear, Tears Naturale) are used for tear replacement; solutions that contain polyvinyl alcohol may be irritating, however. Ophthalmic decongestants (e.g., Visine, OcuClear) are of essentially no therapeutic worth; they obscure the diagnosis and may cause chronic conjunctivitis.

137.12 URINARY INCONTINENCE DRUGS

In 2000, phenylpropanolamine was completely withdrawn from the U.S. market due to its association with hemorrhagic stroke in humans. Although no such link has been noted in veterinary medicine, the lack of OTC phenylpropanolamine has increased interest in pseudoephedrine (e.g., Sudafed 30 mg or 120 mg tablets; also in many cold/flu products [see cough syrups, above]) as an alternative drug for controlling urinary incontinence at a starting dose of 0.1 to 0.2 mg/lb (0.2 to 0.4 mg/kg) by mouth every 8 to 12 hours. Clinical evaluation of pseudoephedrine for urinary incontinence in dogs is limited; higher doses of 15 or 30 mg by mouth every 8 hours to dogs weighing less than or more than 55 lbs (25 kg), respectively, have effectively controlled signs of incontinence with no recorded side-effects. However, a narrow margin appears to exist between therapeutic and toxic doses of pseudoephedrine in some dogs, with clinical signs occurring with single-dose ingestions of 2.2 to 2.8 mg/lb (5 to 6 mg/kg) and deaths with ingestions of 4.5 to 5.4 mg/lb (10 to 12 mg/kg). The high concentration of drug in tablets can make exact dosage more difficult in small dogs; choosing other medications, or meticulous preparation of exact doses, may be preferable for these patients. Advocation of the use of pseudoephedrine should be cautious, and with an understanding of the possible, common adverse reactions (e.g., restlessness, excitement, and tachycardia), which could be detrimental, particularly in patients with cardiac or neurologic diseases.

Over-the-counter drugs may be useful in specific therapeutic situations in which convenience, lack of an effective veterinary equivalent, or cost play an important role in drug selection. These advantages need to be weighed against the drawbacks of drug formulations meant for humans, frequent lack of proven efficacy, absence of veterinary labeling for these products, and the potential for selection of the wrong product by the client.

138 CHAPTER • 138 Compounding Drugs

Ron Johnson

For drug therapy to be considered rational, practitioners must ensure that administration of the drug is safe and efficacious for its intended use. Veterinary medicine does not have a plethora of U.S. Food and Drug Administration (FDA)–approved animal drugs and dosage forms. Added to this dilemma is the need to treat several species of different sizes and biologic make-ups. Compounded drugs can alleviate some of the drug-related issues that face veterinary medicine, provided compounding is approached in a rational manner. The Animal Medical Drug Use Clarification Act (AMDUCA) of 1994 legitimizes compounding from approved animal and human drug dosage forms provided certain criteria are met.[1,2] In this context, compounding is defined by the FDA as any manipulation of the product to produce a drug dosage form other than that manipulation provided for in the directions for use on the labeling of the approved drug product.[2] This form of compounding results in extra-label use of the approved drug product. Compounding from unapproved drug products and bulk products (active ingredient in the unfinished form) are also possible. To encompass these situations, a more general definition of compounding is needed. This includes the preparation of therapeutic compounds that utilize active ingredients and vehicles obtained within the law.

138.1 PHARMACOLOGY CONSIDERATIONS WHEN COMPOUNDING IN COMPANION ANIMALS

Veterinarians need to understand the pharmacologic issues associated with the use of compounded drugs in their patients. Although the decision to compound can be necessary and acceptable under certain conditions, it should not be driven by convenience or economics. Rather, rational therapy based on scientific justification should prevail. The mixing or combining of drugs or the addition of diluents (e.g., lactated Ringer's solution), vehicles (e.g., propylene glycol, dimethylsulfoxide), or flavoring agents to a drug may produce a chemical or physical interaction that renders the product inactive and yields therapeutic failure or may produce a potentially toxic compound. These forms of drug interactions are pharmaceutical interactions or incompatibilities and are demonstrable *in vitro*, that is, outside the body. Manipulations of the dosage form can also result in contamination of a sterile product meant for injection or affect drug bioavailability through alterations in drug release rates.

Compounding by medical professionals and pharmacists is not equivalent to the formulation of commercially manufactured products by reputable pharmaceutical firms. Drug formulation requires an immense understanding of the physical and chemical characteristics of the active ingredient, along with the other agents (e.g., vehicles, excipients) used to produce the administered drug's effectiveness and safety profile. To this end, a compounded drug must possess adequate potency and purity and demonstrate stability (shelf-life) to maintain acceptable bioavailability (extent of systemic drug absorption) of the active ingredient but not produce toxicity or adverse effects. However, for most drugs compounded by veterinarians or pharmacists, there is a lack of adequate pharmaceutical testing and clinical testing to ensure drug quality. Because safety, efficacy, and drug pharmacokinetics have not been determined for most compounded products, and likely not to be, it is important for the veterinarian to establish objective parameters, which indicate whether the compounded product is efficacious, subtherapeutic, or toxic.[3] Objective parameters can include hematologic or clinical chemistry changes, serum drug levels when drug monitoring is available, clinical signs, and clinical end-points.

138.2 COMPOUNDING BY THE VETERINARIAN VERSUS PHARMACIST

Compounded products for use in veterinary medicine must be prepared either by the veterinarian in conjunction with a valid Veterinarian-Client-Patient Relationship (V-C-P-R) or by a licensed pharmacist under the order of the veterinarian. Some of the reasons for employment of compounded drugs in animals include the lack of FDA-approved animal product at an appropriate concentration, drug formulated in a usable dosage form, or available in the required combination.

Requests to pharmacists from veterinarians for compounded prescriptions often surround reformulation of human-labeled drugs for use in companion animals, particularly tablets and capsules.[4] Requests for the mixing of multiple drugs in a single product and formulation of novel systems for drug delivery such as transdermal gels are also increasing. Palatability concerns with various oral preparations have seen the use of flavoring agents to enhance preparation acceptability. Most pharmacists will compound drugs for veterinarians; however, care must be exercised with the selection of a compounding pharmacist. With the need for compounding on the rise, many pharmacists have become members of societies dedicated to reputable compounding, such as the International Academy of Compounding Pharmacists or the Professional Compounding Center of America. Pharmacists with advanced training in compounding can provide valuable expertise and should be sought when the decision to use a compounded drug is made by a veterinarian. Veterinary organizations such as the American Veterinary Medical Association, the American College of Veterinary Clinical Pharmacology, and the American Academy of Pharmacology and Therapeutics along with published literature in reputable journals also represent valuable sources of information on compounding for animals.

The FDA Center for Drug Evaluation and Research has made available a concept paper that evaluates drug products for human use that demonstrate difficulty when compounded because of reasons of safety or effectiveness.[5] The goal of the paper is to identify drugs that are demonstrably difficult to compound based on several evaluating factors, which are also pertinent to compounding for veterinary use. Among these evaluating factors training, facilities and equipment, testing, and quality assurance provide the clearest argument for separating compounding by the pharmacist versus the veterinarian, when other than minor manipulations to the product are required.[4,5] Product categories found notoriously difficult to compound that should be avoided include sterile products, sustained release products, and most transdermal delivery systems.[5] In contrast, candidates most suited for compounding can include drugs with a wide therapeutic index, and drugs for which therapeutic drug monitoring or quantitative end-point measurement is possible and clinical data regarding their use in the intended species and condition is available.

512 513

138.3 DOSAGE FORMULATION AND STABILITY OF COMPOUNDED PRODUCTS

Compounded preparations must possess acceptable potency, purity, and quality with appropriate labeling and packaging to ensure effectiveness, proper use and safety.* Compounding should be conducted in accordance with good pharmacy practices and relevant scientific literature. Pharmacy facilities used for compounding should have adequate room and equipment and be maintained in a clean and sanitary condition to be effective and prevent contamination and errors. Areas used for preparation of sterile products such as sterile injectables or ophthalmic solutions should be separate from nonsterile compounding areas (Box 138-1).

The stability of a compounded preparation is critical to the determination of an expiry or beyond-use date, after which the compounded product should not be used. When a manufactured product is used as the active ingredient source for compounding nonsterile preparations, the manufactured product expiration date cannot be used to

directly extrapolate a beyond-use date for the compounded product. Whenever possible, drug-specific and general stability data and literature should be consulted prior to compounding. In the absence of stability data applicable to a particular drug and specific compounded preparation, the conservative maximum beyond-use or expiry dates recommendations listed in Box 138-2 may serve as suggested general guidelines for nonsterile compounded drug products, which are packaged in tight, light-resistant containers and usually stored at room temperature.

138.3.1 Transdermal Delivery of Drugs with Organogels

The skin offers an ideal alternative to systemic delivery of drugs in veterinary patients; however, significant interspecies differences in skin structure and function represent potential challenges to this route of drug delivery. Delivery of drugs that use transdermal gels is among the newest drug delivery system being utilized in veterinary medicine. Transdermal gels can be utilized effectively and safely in veterinary medicine and can enhance patient compliance. Absorption of drug via the transdermal route is primarily passive. As such, ideal drug molecules for this route of delivery are low molecular weight (<400 Daltons), lipophilic in nature, and soluble in both water and oil.[7]

513
514

The growing list of drugs available in transdermal gel formulation from compounding pharmacists includes antimicrobials, anticonvulsants, hormones, antineoplastics, prokinetic drugs, analgesics, and anti-inflammatory agents. The vast majority of these compounded products are prepared in a pluronic lecithin organogel (PLO) vehicle. Lecithin is an emulsifying agent that forms a viscous gel when combined with water. Pluronic is a surfactant that enhances the formation of drug-containing micelles in a gel matrix. Together, these carriers can dissolve and deliver either hydrophilic or lipophilic molecules, which makes them convenient for delivery of a variety of chemical agents. The transdermal route of drug delivery provides for several advantages, including owner compliance, patient tolerance, ease of administration, and most importantly, the ability to by-pass first pass metabolism by the liver.[7,8] As such, it is possible to deliver agents with low oral bioavailability. Transdermal gels offer an exciting new mode of drug delivery for the veterinary patient. Although investigations with transdermal delivery of drugs are currently underway, most agents compounded with organogels have had little to no clinical data generated with their use. Therefore the clinician must assess both benefits and risks with this mode of drug delivery.

138.3.1.1 Box • 138-1 Aspects of Dosage Formulation Applicable to Drugs Compounded for Companion Animal Use

1. When formulations require the use of water for compounding nonsterile preparations, purified water must be used.
2. Water used for preparation of a sterile product must be either: (a) water for injection, (b) sterile water for injection, or (c) bacteriostatic water for injection.
3. When compounding any formulation starting with a solid material or component, the particles should be reduced to the smallest reasonable size before mixing.
4. When compounding emulsions, solutions, or suspension dosage forms, or semisolid dosage forms such as creams, ointments, topical gels and pastes, an excess amount of the total formulation should be prepared to ensure the prescribed amount can be accurately dispensed.
5. Solutions should contain no visible undissolved materials when dispensed to the client.

6. Emulsions and suspensions should contain instructions to “shake well before using” to ensure uniform dispersion of the active ingredient.

7. Creams, topical gels, ointments, and pastes should not be prepared with ingredients that are irritating or caustic to the skin, and appropriate vehicles or bases should be employed to achieve the desired local or systemic therapeutic effects.

8. The uniformity of dispersion of the compounded gel, cream, ointment, or paste should be assessed by spreading a thin film of finished product on a flat transparent surface, e.g., clear glass.

138.3.1.2

Box • 138-2 Guidelines for Maximum Expiry Dates for Nonsterile Compounded Drug Products

1. For solid dosage formulations and nonaqueous liquids where the manufactured drug product is the active ingredient source, the beyond-use date should not exceed 25% of the time remaining until the manufactured products expiration (or 6 months, whichever is earlier).

2. For water-containing formulations prepared from active ingredients in solid form such as bulk drug (active ingredient in the unfinished form), capsules or tablets, the beyond-use date should not exceed 14 days from preparation when the compounded product is cold-stored.

3. For other formulations, the beyond-use date should not exceed the duration of therapy (or 30 days, whichever is earlier), unless supportive stability date for the compounded preparation exists.

* Information presented in this section, including recommendations and precautions regarding dosage formulation and expiry dates of compounded drugs listed in Boxes 138-1 and 138-2, respectively, can be found in the United States Pharmacopeia and National Formulary.[6]

138.4 REGULATION OF COMPOUNDING FOR VETERINARY MEDICINE

The FDA Center for Veterinary Medicine (CVM) provides regulatory surveillance and enforcement of drug compounding for veterinary medicine under the authority of the Food and Drug Cosmetic Act. The circumstances whereby compounding from approved drugs (animal and human) for animal use by veterinarians is legal can be found in the contents of AMDUCA.[1,9] The FDA-CVM does recognize the need, in limited situations, to compound products from unapproved drugs and occasionally from bulk drugs, provided certain conditions are met. Compliance Policy Guideline 7125.40 was written by the agency to outline guidelines for compounding from approved animal and human dosage form drugs, and unapproved drugs and bulk drugs that ordinarily will not merit regulatory action even though they are technically in violation of AMDUCA.[1] The latter is termed *regulatory discretion*.

Recent FDA concerns regarding compounding have focused on pharmacies that generate large amounts of unapproved drugs for animal use that are largely copies of FDA-approved drugs. These practices constitute attempts to by-pass the drug approval process and can be construed as illegal manufacturing disguised as compounding. The purpose of compounding by a veterinarian or pharmacist under the order of a licensed practitioner is to prepare an individualized drug treatment and not manufacture products for resale.[3,4] Summary recommendations for compounding drugs for use in companion animals are found in Box 138-3.

138.4.1 Box • 138-3 Recommendations for Compounding Drugs for Companion Animal Use

1. The use of compounded drugs should be based on rational therapy originating from a veterinarian and not a pharmacist.
2. Compounding drugs to provide appropriate medical therapy may be necessary when (a) a legitimate medical need exists such as suffering or death resulting from a lack of treating the affected animal, (b) an appropriate dosage regimen does not exist for the species, size, age, or medical problem of the intended animal, or (c) there is no marketed approved animal or human drug available to treat the condition or there is reason to believe the approved drugs will not be efficacious or safe in the intended animal.
3. Compounding must be conducted within the limits of a legitimate pharmacy or veterinary practice.

   Legitimate Pharmacist: A person dispensing pharmaceuticals based on a valid prescription while holding a valid license and conforming to state laws.

   Legitimate Veterinarian: A person prescribing or dispensing pharmaceuticals based on a valid Veterinarian-Client-Patient Relationship while holding a valid license and conforming to state laws.
4. The advice or assistance of pharmacists dedicated to reputable compounding should be sought.
5. Compounded drugs dispensed by a veterinarian (or pharmacist) should contain adequate labeling information to ensure safe and acceptable product use and patient records must be kept.
6. Compounded products should be sold to the individual client and not to other veterinarians or pharmacists for resale.

139 CHAPTER • 139 Nutraceuticals

John E. Bauer

Development of complete and balanced formulated pet foods has been the foundation for dietary recommendations in small animal practice. Modern veterinary nutrition and food manufacturing techniques have culminated in consistent and reliable “functional food” products. Their use is not likely to be abandoned and improvements continue to be made. Nonetheless, many individuals who are interested in dietary supplements, functional foods, and beverages (e.g., nutraceuticals) are also pet owners who wish to provide an extra margin of nutritional benefit for their companion animals. Thus it is no surprise that functional ingredients, treats, supplements, and even beverages have begun to appear that are specifically designed for dogs and cats. These owners see maintaining companion animal health and seeking optimal nutrition for dogs, cats, and other companion animals as an important component of responsible pet ownership. With the myriad products and supplements currently available, veterinary health professionals are often asked to comment on the use of these materials and may find themselves recommending some of them for pet health management. Thus it is important to obtain a better understanding of nutraceuticals, supplements, and functional food ingredients.

139.1 REGULATORY ASPECTS

Legal definitions for the term *nutraceutical* do not exist, although the word was originally coined to refer to any substance that can be administered orally (as are foods) to promote good health and that is not a drug.[1] The Food and Drug Administration (FDA) defines a food as a substance that provides nutrition, taste, or aroma.[2] By comparison a drug is a substance that is either a food or non-food substance used to treat, cure, mitigate, or prevent disease.[2] Drugs, by law, must undergo an approval process that substantiate their safety and efficacy. Therefore an important distinction between a food and a drug exists. In the midst of these definitions, nutraceuticals have found a place for themselves somewhere between foods and drugs. One of the well-known examples of such a substance is fish oil, available in gel capsules from several manufacturers. These and other such substances are in use today in veterinary practice.

The Dietary Supplement Health and Education Act (DSHEA) was passed by the U.S. Congress in 1994. This act facilitated the availability of various nutritional products and supplements for human beings because it considered dietary supplements as a separate food category. It also opened the possibility of certain types of claims (i.e., structure/function claims) to be made without having any scientific evidence submitted to the FDA prior to marketing. However, DSHEA applies only to human foods. Discussion of animal dietary supplements was left out of the deliberations.

With respect to animal foods, responsibility for enforcing all aspects of the Food, Drug and Cosmetic Act that may apply to foods and drugs for animal use rests with The Center for Veterinary Medicine (CVM) of the FDA. This group is involved in reviewing food and feed additives. For reasons beyond the scope of this chapter, the CVM has essentially assigned “low regulatory significance” to most nutraceuticals. As a result, individual states were left to rule on market access to these substances.[3]

139.2 CLINICAL USE

It is helpful to know that, although the DSHEA governs human dietary supplements, this act is generally interpreted by the FDA's CVM office to not apply to animals.[4] However, pet owners often purchase nutraceuticals

and other supplements labeled for human use and administer them to their pets. What, then, should be the basis for veterinary recommendation of a specific substance?

139.3 GENERAL GUIDELINES

In the absence of a science-based regulatory consensus, the best advice is to proceed cautiously and seek out new information as it becomes available. Scientific data about certain substances is often unknown or incomplete, although they may be promoted as if conclusive evidence exists.

Four important types of information should be borne in mind during consideration of the use of a particular dietary supplement in companion animals. This type of information ideally should be known prior to recommendation of any widespread or long-term nutraceutical usage. The more gaps that are found in a particular substance's information profile, the more cautiously one should proceed regarding dosage, indications, and patient monitoring. These four categories of information can be easily recalled using the acronym *PETS* (Product Quality, Efficacy, Tolerance, and Safety) and can be used to assist discussions with clients about a particular supplement.

139.3.1 Product Quality (P)

The product quality of a substance should be documented and available. Independent of any scientific proof of efficacy or safety (discussed below) if a product is making a structure/function claim, it must first contain an amount within a realistic concentration range of potential efficacy and safety. Some manufacturers reportedly place a small amount of a popular ingredient in a product, which then allows what is termed "label dressing."[5] This practice is not highly regarded among reliable manufacturers. Also, manufacturers should be knowledgeable about their product, its formulation, and ingredient sources.

For the most part, nutritional supplements should be considered chemicals rather than commodities such as grains or protein meals. Each batch the manufacturer receives should have specifications as to its purity. Some preparations may contain less of the "active" material, which is all right as long as the product is formulated to provide enough of the ingredient and as long as there are no harmful or interfering materials present. To some extent, the cost of a substance may reflect its quality but not always. Individual distributors should be consulted for further information regarding the manufacturer. The manufacturer then may be contacted for answers to any questions regarding product quality. The answers should include information on specifications and what other substances may be present in the product formulation. The manufacturer should readily supply quality control and other supporting information when requested. This latter point may be an important part of any decision to use a particular product. Any reluctance on the part of the manufacturer or distributor to provide information should warrant finding another source of that particular substance.

515 516

139.3.2 Efficacy (E)

Efficacy of any therapy is established by scientific testing. Demonstrating efficacy of a nutraceutical substance requires rigorous and often expensive testing, depending on the extent to which claims for a product are being made and the regulatory environment surrounding that substance. Manufacturers should be asked to supply supportive documentation of efficacy. This information may be proprietary, but reprints of articles and other information should be available upon request. If supporting information is not offered, another product should be selected and the process begun again. Any materials sent should be reviewed with the following questions in mind: What is the active ingredient? Are there several active ingredients acting together? Have any efficacy studies been performed in the species of interest (target species) and, if not, in other species? Were the studies

controlled and published under peer-review? Was the same dose used in the studies as is now being recommended for the product?

139.3.3 Tolerance (T)

Tolerance for any nutraceutical must exist for it to be effective. It must be acceptable by the animal and to the pet owner. For example, administering fish oil capsules to dogs is a simple task because most dogs will readily accept them as treats. However, some animals may smell “fishy” and owners may object. Administering fish oil capsules to cats is more difficult, especially if a cat happens to bite into a capsule and develop a taste aversion. In some cases, the inert ingredients that often serve as dispersants or diluents may cause an adverse reaction. An example is the flatulence that may occur due to inclusion of a fermentable fiber. The net effect may result in erroneously shifting blame on the pet food rather than the supplement. Alternatively, product intolerance may cause an owner unnecessary expense in searching for some medical reason for the problem. Milk sugars, such as lactose, may cause gastrointestinal upset, diarrhea, or vomiting. Eliminating the supplement or changing to another product to eliminate these inert materials may be all that is required. However, veterinary personnel must remember to think of these possibilities when owners' insist on using supplements. Also, it must be identified what other medications that animal is receiving. An interaction with the nutraceutical may be occurring, which would render traditional therapies useless.

139.3.4 Safety (S)

Safety is paramount and must be known before using a dietary supplement, as expressed in the dictum, “Above all else, do no harm”? Historical data on usage of certain substances may provide practical information regarding safety. Using a particular supplement in the absence of any published safety data in the target species is particularly risky and caution is advised. Also, lack of reports in the literature of any adverse effects should not be interpreted to indicate safety. The cost and expense to conduct safety studies may be more than some supplement marketers may wish to incur. Even for those substances for which such data is provided, caution is warranted: as the actual concentrations and purities of a particular substance can vary from source to source.

Many pet owners will be administering nutraceuticals to their pets regardless of veterinary advice or supervision. Labels of any products used should list the ingredients along with their amounts and purity in decreasing order of concentration based on weight. Directions for use and other requisite guarantees should be included on the label depending on state feed regulations for specific, more traditional components, such as crude protein, crude fat, fiber, ash, and moisture. Herbal type products should be especially evaluated with caution due to potential toxicities and product quality concerns.

With increased interest in human supplement usage, the opportunity for accidental ingestion of nutraceuticals by companion animals also exists. A recent report summarized 47 dogs suspected of caffeine and ephedrine toxicosis that had access to herbal preparations that contained guarana and ma huang.[6] Clinical signs included the full gamut of those associated with the gastrointestinal tract, CNS, and cardiopulmonary system. Amounts of guarana (caffeine) and ma huang (ephedrine) ingested by these dogs ranged from 80 to 3600 mg of guarana and 24 to 1080 of ma huang.[6]

The ready availability of supplements in retail outlets, by mail order, and the Internet along with supporting brochures may be all that many pet owners need to conclude that a particular product is safe. Clients must be made aware of health concerns with use of an unproven substance against the veterinarian's best judgment. Any dietary histories taken must include the use of any nutraceutical type substances.

139.4 NUTRACEUTICALS OF CURRENT INTEREST

Although scientific data in target species remains limited for many types of nutraceuticals, some usage categories of pet dietary supplements and ingredients presently are receiving closer attention by the pet industry and veterinarians. Two of these categories include joint soundness and skin health. Antioxidants are also gaining becoming more popular and these are covered in a separate chapter.

139.4.1 Joint Health

Improvements in pet food quality and feeding practices combined with better veterinary care has resulted in increased longevity of companion animals. However, as with human beings, increased life expectancy has increased the risks for the development of chronic, progressive disease such as osteoarthritis, obesity, renal failure and their complications. With increased age, the genetically influenced degenerative diseases such as intervertebral disk disease, hip dysplasia, cognitive disorders, and familial disorders may also become exacerbated. In addition to specialty foods containing substances with purported benefits, a number of supplement products have been developed in response to improving joint and bone health. Some of these substances are glucosamine, chondroitin sulfate, green-lipped mussel, methylsulfonyl methane, and trace minerals such as zinc, copper, and manganese. Many products use combinations of some but not all of these materials. Although it is often difficult to scientifically prove that one particular substance is efficacious when combined with others, there is growing evidence that some of these products have a beneficial effect on joint health. Some mention will be made of combination products that are available. However, to the extent possible, the discussion focuses on effects of single agents such as glucosamine and other compounds.

516

517

Glucosamine is an amino sugar that is naturally produced in the body. It is a component of glycosaminoglycans (GAGs) present in joints, tendons, ligaments, skin, and blood vessels. The GAGs are long chain molecules that can hold water and allow the joint capsule to adapt to changes in pressure and therefore absorb shock induced by mechanical stress. Destruction of cartilage is characterized by destruction of the GAGs and loss of this property of the joint capsule. Theoretically it is expected that provision of supplemental glucosamine to joint issues will stimulate new GAG production. Data demonstrates that glucosamine can be absorbed via the gastrointestional tract in dogs after oral ingestion and is taken up by articular cartilage.[7]

A biochemical basis for the use of glucosamine in treatment of chronic inflammatory disease has also been shown in the rat model of lipopolysaccharide-induced inflammation. Here it was found that glucosamine inhibits inducible nitric oxide synthesis. Excess nitric oxide mediates the pathogenesis of osteoarthritis.[8] Recently, in human osteoarthritis patients, the long-term effects of glucosamine sulphate have been evaluated using a randomized, placebo-contolled clinical trial (1500 mg orally).[9] Symptom-modifying and structure-modifying effects were found, which suggests the compound could mitigate osteoarthritis. Regarding the safety of this compound, no significant differences in adverse events compared with placebo were found.[9]

Long-term safety studies of the chondroprotective agents in dogs or cats have not been reported. However, one caveat regarding the widespread use of glucosamine should be noted. Glucosamine infusions in ducks and dogs have been reported to cause hyperglycemia due to the release of glucagon immunoreactivity and possible insulin suppression.[9,10] Similarly in human beings, glucosamine infusions produced acute insulin resistance[11] and glucosamine may also induce or exacerbate insulin resistance.[12]

Thus, in cases of diabetes or possibly even obese animals prone to type II diabetes, the use of glucosamine may be contraindicated. An anecdotal report using a high oral dose of glucosamine (1000 mg/day, duration unspecified) in an 11 year-old Labrador retriever noted urinary incontinence, polyuria, and polydipsia, which abruptly returned to normal when the dosage was reduced to 500 mg/day.[13] However, serum glucose concentration tested using a midday, nonfasted sample was normal and follow-up tests were not conducted in this dog. By contrast, one study in rats was unable to demonstrate adverse effects of glucosamine or chondroitin sulfate on glucose metabolism.[14] Until more usage data is obtained, caution is advised and patients should be carefully monitored, especially if higher dosages are being used or considered.

With respect to other chondoprotective agents, data exist that support an interactive, or synergistic, effect between glucosamine and chondroitin sulfate in helping maintain joint health. Combinations of glucosamine with other products that contain mucopolysaccharides or other substances may help alleviate joint problems or rebuild degenerating cartilage. One proprietary product in particular, which combines glucosamine with chondroitin sulfate and manganese ascorbate, has been subjected to several cell culture and animal studies in dogs and other target species.[15–18] Survey data of practicing veterinarians have provided information that pain relief as well as mobilility was good to excellent with this type of combination product.[16]

Other substances that may benefit joint health include methylsulfonylmethane (MSM) and green-lipped mussel extracts. Purported benefits of MSM relate to it as a bioavailable source of sulfur, which is a component of several structural compounds found in joints.[19] The use of MSM in dogs or cats remains to be evaluated. Studies using green-lipped mussel extract, a mixture of glucosaminoglycans and omega-3 fatty acids and possibly other compounds, have been inconsistent in dogs exhibiting chronic lameness.[20,21] Additional proprietary combinations have also been evaluated.[22,23] In these cases, potential benefits of glucosamine may be further enhanced by the addition of other known collagen-matrix components or even anti-inflammatory agents.

As additional findings of both proprietary mixtures and single substances are reported, further confidence in the safe and efficacious use of chondroprotective materials, in certain clinical cases, will develop. However, at present, caution is advised with these agents in dogs and cats, especially the use of glucosamine compounds in animals at risk for diabetes.

139.4.2 Skin Health

When animals have skin problems, a full dermatologic work-up should be conducted rather than simply using diet or dietary supplements in the hopes of improvement. Shampooing, brushing, and use of moisturizers are significant components of skin care. Ensuring that the animal is fed a well-formulated diet is also important. Supplementation with therapeutic amounts of fatty acids or diet change is generally considered where animals are pruritic due to hypersensitivity reactions, exhibit dry, flaky skin, or have suspected abnormalities of fatty acid metabolism.

Omega-6 fatty acids (e.g., linoleic acid) are used preferentially for select functions. These include incorporation into the lipid ceramide layer of the epidermis, which imparts its water-barrier character or their provision of precursors for physiologically important eicosanoid synthesis to help maintain cell membrane integrity.[24,25] The omega-3 fatty acids, especially long chain types from marine oils (>18 carbon chain length), are noted for their preferential role in neurologic development and potential for reduced inflammatory response.[25,26] The plant-derived 18 carbon omega-3 fatty acid, alpha-linolenic, may also play a supportive role in the

inflammatory response. However, their limited conversion to active long-chain derivatives and favored use as substrate for energy requires substantially greater dietary amounts to achieve such an effect compared with supplying the already-formed long chain active fatty acids.[27,28] The 18 carbon omega-3 fatty acids are not as potent a source for the above desired effects as are the 20/22 carbon types. Products that contain both 18 and 20/22 carbons omega-3 acids should have their labels carefully scrutinized as to the source, types, and amounts of the various fatty acids. The dosage needed will be different, depending on the intended use of the product.

Should a therapeutic supplement of dietary omega-3 fatty acids be desired (i.e., as an adjunct to atopy treatment or inflammatory condition), an oil supplement containing 100% fish or other marine oil should be used. Conversely, if redness and inflammation is not present, selection of a proprietary blend that contains both omega-6 and omega-3 fatty acids, or simply 1 teaspoon per 10 lb body weight of a liquid vegetable oil daily should be sufficient in most instances. Although the clinical efficacy of fatty acid supplements is considered only modestly effective[29], a recent study has shown significant short-term improvements in skin and hair coat scores of clinically normal dogs when fed either linoleic (omega-6) or alpha-linoleic (omega-3) acid supplements.[30] Another study found a synergistic effect using linoleic acid, zinc, and biotin noting a reduction in hair coat scaliness scores.[31] Finally the safety of dietary fatty acid supplements in the amounts recommended above and in the literature appear to be well tolerated. However, it should be noted that extra calories are present in fatty acid or vegetable oil supplements (approx. 9 kcal/g) so caution is advised especially in small companion animals prone to obesity.

140 CHAPTER • 140 Nonsteroidal Anti-Inflammatory Analgesics

Karol A. Mathews

Nonsteroidal anti-inflammatory analgesics (NSAIAs) are a group of pharmaceutical agents that possess analgesic and anti-inflammatory properties. The NSAIAs are frequently used in human and veterinary medicine to relieve mild, moderate, and severe pain. The efficacy of many recent NSAIAs can compare to the pure mu agonist opioids (morphine, oxymorphine, hydromorphine) in managing soft tissue and orthopedic post-operative pain[1,2]. When used in combination with opioids, NSAIAs appear to confer synergism and may require reduced dosing of the opioid. The NSAIAs concentrate in inflamed joints and tissues, which likely contribute to duration of effect, which varies between 12 and 24 hours.[3] The duration and efficacy of the NSAIAs makes them ideal for treating acute and chronic pain in veterinary patients; however, due to their potential for harmful adverse effects, animal and NSAIA selection must be considered prior to administration (Table 140-1).

140.1 PHARMACOLOGY

A significant part of the NSAIAs' antinociceptive effects is exerted at the spinal cord and supraspinal levels.[4] This action, in addition to pain relief, may account for the observed overall well-being and improved appetite of animals that receive injectable NSAIAs for relief of acute pain. Nonsteroidal anti-inflammatory analgesics are, with varying differences, inhibitors of cyclooxygenase enzyme-1 (COX-1), COX-2 or both, which result in reduced prostaglandin synthesis. Cyclooxygenase-1 is increased approximately two-or three-fold in tissue injury and therefore is involved in pain transmission but to a lesser degree than COX-2. With respect to pain, COX-2 is inducible and synthesized by macrophages and inflammatory cells, potentially increasing by 20-fold over baseline, in the presence of tissue injury and inflammation.[4] Increased cyclooxygenase levels increase prostanoid production, where these compounds mediate inflammation and amplify of nociceptive input and transmission in both the peripheral and central nervous systems.[4] By this mechanism, COX-2 is responsible for most of the pain and hyperalgesia experienced after tissue injury.

Based on these findings emphasis is placed on COX-1 versus COX-2 activity of NSAIAs, with respect to safety and efficacy. However, both have important constitutive functions and the notion of “good versus bad COX” is not an “all-or-none” event. COX-1 is a constitutive enzyme, present in tissues, that ultimately converts arachidonic acid into prostanoids (thromboxanes, prostacycline, and prostaglandins [PG]E_2, PGF_2 and PGD_2).[5] The most common, and clinically apparent, potential adverse effects of a COX-1 preferential NSAIA is the reduction in activity of these prostanoids and consequently affect primary plug formation of platelets, modulation of vascular tone at the level of the kidney, and inhibition of cytoprotective functions on the gastric mucosa.[5] These actions are frequently noted with respect to prostaglandin activity.

However, prostaglandins are ubiquitous throughout the body and regulate many other functions. For example, these functions include thermoregulation and vascular and bronchial smooth muscle tone. Prostaglandins exert a negative feedback effect on cyclic adenosine monophosphate (c-AMP) with potential perturbations in many physiologic functions. As an example, renal water reabsorption depends on the action of antidiuretic hormone (ADH), which is mediated by c-AMP; inhibition of PG (prostaglandin) synthesis may lead to increased levels of c-AMP with a potential for enhanced ADH activity. Urine volume may be decreased through this mechanism but without renal injury.[5,6] Cyclooxygenase-2 has some important constitutive functions; there may be a protective role for COX-2 in maintenance of gastrointestinal integrity, ulcer healing, and experimental colitis in rats. In

addition, there is constitutive activity associated with nerve, brain, ovarian and uterine function, and bone metabolism.[6] Most importantly, COX-2 has constitutive functions in the kidney, which differ from those of COX-1. The COX-2 is important in nephron maturation.[7] The canine kidney is not fully mature until 3 weeks after birth; continual administration of a NSAIA during this time, or to the bitch prior to birth, may cause a permanent nephropathy. On the other hand, COX metabolites have been favorably implicated in functional and structural alterations in glomerular and tubulointerstitial inflammatory disease.

Administration of COX-2 selective inhibitors decreased proteinuria and inhibited development of glomerular sclerosis in rats with reduced functioning renal mass.[7] Because COX-2 expression is also increased in glomerulonephritides such as lupus nephritis, it is possible that COX-2 inhibitors may also alter the natural history of glomerular inflammatory lesions.[7] The COX-2 derived metabolite production is regulated and localized to the structures in the kidney that plays an essential role in renal blood flow associated with renin activity and fluid-electrolyte homeostasis.[2] Cyclooxygenase-2 is glucocorticoid sensitive, in that it is reduced after administration of glucocorticoids, which may partially explain the anti-inflammatory and analgesic effects of this class of medications. Of interest, in addition to the COX-2 role in inflammation, aberrantly upregulated COX-2 expression is increasingly implicated in the pathogenesis of Alzheimer's disease and possibly other neurologic conditions and a number of epithelial cell carcinomas, including colon, esophagus, breast, and skin.[8,9] The COX-2 inhibitors are being researched as potential anticarcinogenic agents. Associated with the use of NSAIAs is the risk of purturbation of the constitutive functions of COX-1 and COX-2, resulting in potential organ dysfunction. However, “not all NSAIAs are created equal” in this regard. Some NSAIAs have both COX-1 and COX-2 inhibitory effects (aspirin, ketoprofen, ketorolac), whereas others preferentially inhibit COX-2 or are COX-1 sparing to varying degrees (meloxicam, carprofen, etodolac, tolfenamic acid).

As the COX-2 appears to play a significant role in nociceptive transmission, medications that prevent COX-2 activity and spare COX-1 should be effective, with potentially less adverse effects, in the management of pain. The COX-2 specific inhibitors (rofecoxib, celecoxib), currently available in human medicine, appear to have less 518
gastrointestinal adverse effects than other NSAIAs. However, long-term use in some people has resulted in similar 519
gastrointestinal problems as those experienced with commonly used NSAIAs; therefore it cannot be assumed that these NSAIAs will be a safe treatment for all cats and dogs with chronic administration. The COX-2 specific NSAIAs are currently being investigated in veterinary medicine. At the time of publication, deracoxib has recently been approved for control of postoperative pain and inflammation associated with orthopedic surgery in dogs. The incidence of vomiting and diarrhea were similar in dogs receiving deracoxib compared with dogs that received placebo in a perioperative field trial; however, overall the drug was well tolerated and effective. A good review of “the Coxibs” is available.[8]

Table • 140-1 Nonsteroidal Analgesic Dosing Regimen Per Body Weight*

DRUG	INDICATION	SPECIES, DOSE, ROUTE	FREQUENCY
Ketoprofen	Surgical pain	Dogs: ≤2.0 mg/kg, IV, SC, IM, PO	Once postoperative
		Cats: ≤2.0 mg/kg, SC	Once postoperative
		Dogs and cats: ≤1.0 mg/kg	Repeat q24h
	Chronic pain	Dogs and cats: ≤2.0 mg/kg, PO	Once
		≤1.0 mg/kg	Repeat q24h
Meloxicam	Surgical pain	Dogs: ≤0.2 mg/kg IV, SC	Once
		≤0.1 mg/kg IV, SC, PO	Repeat q24h
	Chronic pain	Dogs: ≤0.2 mg/kg PO	Once
		≤0.1mg/kg PO	Repeat q24h
	Surgical pain	Cats: ≤0.2 mg/kg SC, PO	Once
		≤0.1mg/kg SC, PO lean weight	Daily for 2 to 3 days
	Chronic pain	Cats: ≤0.2 mg/kg SC, PO	Once
		≤0.1 mg/kg PO lean weight	2 to 3 days
		0.025 mg/kg PO lean weight (~0.1 mg/CAT max)	3 to 5 times weekly
Carprofen	Surgical pain	Dogs: ≤4.0 mg/kg, IV, SC ≤2.2 mg/kg PO	Once upon induction
			Repeat q12h-24h PRN
		Cats: ≤2.0 mg/kg SC lean weight	Once upon induction
	Chronic pain	Dogs: ≤2.2 mg/kg PO	q12h-24h
Etodolac	Chronic pain	Dogs: ≤10–15 mg/kg PO	Once daily
Deracoxib	Peri-operative pain	Dogs: 3.0 mg/kg PO	Once daily for 7 days
	Chronic pain	Dogs: 1–2 mg/kg PO	
Tepoxalin	Chronic pain	Dogs: 10 mg/kg PO	Once daily
Tolfenamic acid	Acute and chronic pain	Cats and dogs: ≤4 mg/kg SC, PO	Once daily for 3 days. 4 days off. Repeat the cycle
Flunixin	Pyrexia	Dogs and cats: 0.25 mg/kg SC	Once
Meglumine	Ophthalmologic procedures	Dogs and cats: 0.25–1.0 mg/kg SC	q12h-24h PRN for 1 or 2 treatments
Ketorolac	Surgical pain	Dogs: 0.3–0.5 mg/kg IV, IM	q8h-q12h for 1 to 2 treatments
		Cats: 0.25 mg/kg IM	q12h for 1 to 2 treatments
	Panosteitis	Dogs: 10 mg/DOG ≥30 kg, PO	Once daily for 2 to 3 days
		5 mg/DOG >20 kg <30 kg, PO	
Piroxicam	Inflammation of the lower urinary tract	Dogs: 0.3 mg/kg, PO	q24h for 2 treatments, then
			q48h
Acetaminophen	Acute or chronic pain	Dogs only: 15 mg/kg PO	q8h
Aspirin	Acute or chronic pain	Dogs: 10 mg/kg PO	q12h

Modified with permission.

* See text for details on the contraindications for use.

Recently reported cloning and expression of canine COX-1 and COX-2 reveal these enzymes to be highly homologous to their human counterparts. Assays developed to assess the potency of inhibition of the canine cyclooxygenases by various NSAIAs indicated no difference from their potency on human enzymes, maintaining the same rank order of potency. The researchers concluded that any differences that may occur *in vivo* between

canine and human inhibition of COX-1 and COX-2 can be attributed to factors other than inhibition of these enzymes.

Most NSAIAs that inhibit COX have been shown to result in diversion of arachidonate to the 5-lipooxygenase pathway. This results in an excessive production of leukotrienes, which have been implicated in the creation of NSAIA-induced ulcers.[5] Tepoxalin, a dual COX/lipooxygenase inhibitor, has recently been approved for management of osteoarthritic pain in dogs. *In vitro,* tepoxalin inhibited COX-1 with at least a thirty-fold higher potency than for COX-2. The potencies for tepoxalin as a lipooxygenase and COX inhibitor, seemed to be in the same range; however, *in vivo* studies showed less potency against lipooxygenase than against COX and efficacy comparable with meloxicam or carprofen and safety comparable to placebo.

519 520

140.2 GENERAL CONSIDERATIONS

The general health of the animal must be considered prior to prescribing NSAIAs. Cats and dogs are more susceptible than people to the adverse effects of NSAIAs. Therefore the reported safety of any drug approved for humans should not be assumed to be safe in dogs or cats. Most NSAIAs require accurate dosing to avoid potential adverse effects, especially when used long term. Anecdotal reports of single, accidental, large overdoses have been reported with no adverse effects; however short-term prophylactic gastric and renal protection may be advised with extremely high overdose.

NSAIAs should be restricted to animals older than 6 weeks of age (may be older depending on the NSAIA) that are well-hydrated and normotensive and have normal renal and hepatic function. Although these are general guidelines, COX-1 sparing NSAIAs may prove safe in animals with non–clinically significant elevations in creatinine and liver enzymes where the benefit outweighs the risk. Some animals may be receiving other medications and NSAIA interaction must be considered.[3]

Plasma levels of NSAIAs are effectively reached within 1 hour after oral administration.[3] When given per os, NSAIAs must be given with food to protect the gastric mucosa from high localized concentrations of the drug increasing the potential for gastric erosion. However, potential for gastric erosion exists with all NSAIAs regardless of route of administration. To reduce this, NSAIAs should be decreased to the lowest possible dose that will confer analgesia. If evidence of gastric erosions/ulcers exists, drug withdrawal and gastroprotective therapy is advised. NSAIA induced renal insufficiency is usually temporary, if identified early, and reversible with drug withdrawal; administration of IV fluids may be required. An increase in serum alanine aminotransferase (ALT) activity can occur with most NSAIAs, is reversible with NSAIA withdrawal, and appears to be of little clinical significance. Rare, acute hepatotoxicity after carprofen administration has been reported in dogs (Labrador retrievers highly represented) in North America[1] but has not been reported in Europe.

140.3 INDICATIONS FOR NSAIA ADMINISTRATION

The indications proposed here assume no contraindications (below) to their use.

1. **Postoperative pain:** Orthopedic[1,2] and selected soft tissue surgical procedures[1,2] may warrant NSAIA administration, especially where extensive inflammation or soft tissue trauma is present. Opioid administration is beneficial immediately after most surgical procedures, due to the sedative and synergistic analgesic effects, to ensure a smooth recovery. Injectable NSAIAs can be co-administered with an opioid initially and subsequently used alone as the repeat analgesic after orthopedic and selected soft tissue surgery. The initial dose of NSAIAs depends on the expected severity of pain. Assuming a difficult fracture

repair would require the recommended loading dose, then a laparotomy without complications, could be successfully treated with half this dose. The administration of NSAIAs prior to surgical procedures is controversial due to their potential for harm. Various studies investigating pre-operative administration of NSAIAs in animals did not specifically screen for adverse reactions.[1] Studies that specifically assess efficacy and safety of NSAIAs given preoperatively, where intraoperative fluid therapy was administered and patient monitoring conducted, noted rare adverse reactions with some of the NSAIAs[1].

A recent study conducted at the Ontario Veterinary College demonstrated no ill effects with the administration of meloxicam or carprofen prior to orthopedic or soft tissue surgery in both cats (meloxicam) and dogs (meloxicam and carprofen) (unpublished data). In these studies, in which intraoperative fluids were administered, the NSAIA did provide very good to excellent analgesia, for longer than 24 hours, in approximately 70% of animals that underwent orthopedic procedures. The remaining animals required a much lower dose of opioid than expected to manage moderate to severe postoperative pain. The benefit of preoperative use of NSAIAs is the potential for a pre-emptive effect and the presence of analgesia upon recovery. Analgesia during the recovery period is essential. The recently released deracoxib is also approved for pre-and post-operative use at 2 mg/kg once daily for 7 days. Where NSAIAs are administered postoperatively, opioids should be administered concurrently because 45 minutes are required for therapeutic effect of the NSAIA. Another potential approach could be to administer the NSAIA upon completion of the surgical procedure at least 45 minutes prior to extubation.

Ketoprofen is an excellent analgesic but is an inhibitor of both COX-1 and COX-2. Therefore unwanted side effects are a potential problem requiring careful patient selection. Ketoprofen should be reserved for postoperative use to reduce the potential for hemorrhage. Flunixin meglumine is used as an antiinflammatory agent in selected ophthalmologic surgical procedures; however, the potential for side effects is of major concern[1] and potentially safer NSAIAs are as effective.

2. **Inflammatory conditions:** NSAIAs appear to be more efficacious than opioids for relief of pain due to meningitis, soft tissue inflammation, polyarthritis, cystitis, otitis, severe inflammatory dermatologic diseases, or injury (i.e., degloving, animal bites). Because many of these animals may be more prone to NSAIA toxicity, careful patient selection and management is advised. Combination opioids and low dose NSAIAs are also effective in these conditions. An exception is necrotizing fasciitis where NSAIAs are reported to increase morbidity and mortality.[1]

3. **Miscellaneous conditions:** Other indications for the use of NSAIAs are panosteitis, hypertrophic osteodystrophy (HOD), cancer pain (especially of bone), radiation-induced stomatitis in cats and dental pain[1]. Non–COX-1–sparing NSAIAs should be used with caution after dental extractions where bleeding is, or may be, of concern. Ketoprofen or ketorolac is suggested for the management of refractory pain associated with hypertrophic osteodystrophy and panosteitis. The HOD of Weimeraners is poorly responsive to NSAIA therapy and is better treated with high dose, short-term corticosteroids, provided infectious disease has been ruled out and clinical signs are consistent with HOD alone.[1]

4. **Osteoarthritis:** Long-term studies of the adverse effects of NSAIAs (carprofen, meloxicam, etodolac) for osteoarthritis, appear to be minimal and are predominantly associated with the gastrointestinal tract.[10] As many animals with osteoarthritis are geriatric a rapid reduction of the dose, to affect a comfortable state, is advised to reduce potential toxicity. For example, alternating to every third day therapy of meloxicam, with half the label recommended dose, proved efficacious in some dogs during a 12-month period.[1] As the long-term dosing of carprofen in Europe is 2.2 mg/kg once daily, potentially reduced dosing for dogs in

North America may also be beneficial. If a particular NSAIA appears ineffective in managing pain, prescription of a different NSAIA may be effective due to individual variation in response to the different analgesics. In situations in which the adverse effects of an NSAIA are a concern, reduction of the dose and addition of an opioid may be equally as effective for chronic severe pain.

However, for many geriatric animals with renal insufficiency and increased serum ALT activity, NSAIAs may be the only effective class of analgesic. For these animals the quality of life is of major importance. In this situation, a COX-1 sparing/COX-2 preferential NSAIA, at the lowest dose possible, may be suggested for both cats and dogs. Anecdotal reports indicate that worsening of renal function may not be a problem in some animals. Client understanding of potential worsening of renal or hepatic function is necessary prior to treatment. Water must be available at all times. Dietary indiscretions and stressful situations must be avoided. During NSAIA therapy all dogs and cats should be monitored for hematochezia or melena, vomiting, increased water consumption, and a nonspecific change in demeanor. If this occurs, the owner should be instructed to stop the medication and consult the veterinarian. Intermittent monitoring of creatinine and ALT is recommended when NSAIAs are prescribed chronically.

140.4 PYREXIA

Most veterinary-approved NSAIAs, aspirin and acetaminophen, are effective antipyretics. The antipyretic effect is obtained with a lower than analgesic dose. Dipyrone is an excellent antipyretic and is available as tablets and solution for injection. Dipyrone should be given intravenously to avoid the irritation when given intramuscularly. The analgesia produced is not adequate for moderate to severe postoperative pain. Gastric ulceration or nephrotoxicity is not a concern in the short term even in critically ill patients.

140.5 CONTRAINDICATIONS FOR THE USE OF NSAIAS

Nonsteroidal antiinflammatory analgesics should not be administered to animals with acute renal insufficiency, hepatic insufficiency, dehydration, hypotension, conditions associated with low “effective circulating volume” (i.e., congestive heart failure, ascites), coagulopathies (i.e., factor deficiencies, thrombocytopenia, von Willebrand's disease), concurrent use of any other NSAIAs or corticosteroids, evidence of gastric erosion (vomiting with or without the presence of “coffee ground material,” melena), or spinal injury (including herniated intervertebral disc) as most of these patients receive corticosteroid with medical or surgical management. NSAIAs should never be administered to animals in shock or those that have been recently traumatized. NSAIAs should not be given if hemorrhage is evident (i.e., epistaxis, hemangiosarcoma, head trauma). Animals with severe or poorly controlled asthma, or other moderate to severe pulmonary disease, may deteriorate with COX-1 inhibiting NSAIAs. The administration of NSAIAs in head trauma, pulmonary diseases, or thrombocytopenia may prove to be safe with further study of the COX-2 preferential/COX-1 sparing NSAIAs. NSAIAs may have adverse effects on the reproductive tract and fetus as they may block prostaglandin activity resulting in cessation of labour, premature closure of the ductus arteriosus in the fetus, and disruption of fetal circulation.[6] As COX-2 induction is necessary for ovulation and subsequent implantation of the embryo,[6] NSAIAs should be avoided in breeding females during this stage of the reproductive cycle.

Topically applied nonsteroidal anti-inflammatory analgesics were significantly more effective than placebo in many human clinical trials involving acute and chronic painful conditions.[1] Topical NSAIAs were not associated with the gastrointestinal adverse effects seen with the same drugs taken orally.[1] At the time of writing this chapter, there are no published studies investigating the use of topical NSAIAs in the veterinary literature.

140.6 NSAIAS NOT APPROVED FOR USE IN VETERINARY PATIENTS (OFF LABEL USE)

Ketorolac parenteral formulation and tablets are comparable to oxymorphone in efficacy and to ketoprofen in duration and efficacy in managing post-laparotomy and orthopedic pain in dogs.[1] Only one to two doses should be administered. Ketorolac is included for the benefit of those working in the human research setting, where the availability of ketorolac is more likely than other NSAIAs. Ketorolac has been used successfully for treatment of severe panosteitis in dogs in which all other therapies had failed. Ketorolac given with food for 2 to 3 days in hydrated dogs resolved signs in approximately 99% of those treated. In the other 1%, signs recurred within a few days to months (unpublished observations). Misoprostol should be coadministered.

Aspirin is available in tablet form. It is most commonly used as an analgesic for osteoarthritic pain in dogs. It is formulated in combination with opioids, aspirin and codeine, or aspirin and oxycodone, for a synergistic effect for the treatment of moderate pain. It is also used as an antipyretic and anticoagulant in dogs and cats.

Acetaminophen is available in tablet form. It may be used as an antipyretic or as an analgesic. It is formulated in combination with opioids, acetaminophen and codeine, or acetaminophen and oxycodone.

Over several years, many studies have reported the safety and efficacy of the commonly used NSAIAs in various clinical settings[1]; similar studies that investigate the use of the recently approved COX-2 specific and dual cyclooxygenase/lipooxygenase inhibitors, with well-designed prospective clinical trials and laboratory studies, should determine the safety and efficacy of these NSAIAs in both the acute and chronic pain management settings.

141 CHAPTER • 141 Antioxidants in Health and Disease

John E. Bauer

Free radicals are molecular fragments that have at least one unpaired electron. This characteristic makes them highly reactive in biologic systems. Their activity can be beneficial because they participate in oxidative burst reactions and other mechanisms that characterize neutrophil and other inflammatory cell function that serve to phagocytose and kill bacterial invaders. However, when free radicals are present in excess, oxidative metabolic damage, and destruction of normal cell membranes, or destruction of cell content may occur. To help keep these mechanisms in check, biologically active scavengers of free radicals help interrupt further cell damage. These scavengers, the antioxidants and related mechanisms, thus normalize the effects of an overabundant and destructive cell process.

Evidence supports the concept that humans who include appropriate amounts of fruits and vegetables in their diet, which are high in antioxidants, appear to lower risk of cardiovascular disease and cancer risk.[1] Specific dietary factors responsible for these benefits are not known. Plant and plant products contain numerous phytochemicals that may play some role. There is a need for carefully conducted studies to determine whether extracted plant or other antioxidant material, when ingested as a single nutrient, would help prevent any specific disease. To date, however, no direct connection has been made between antioxidant consumption and prevention of chronic disease. In some cases overconsumption may even prove harmful.

141.1 ANTIOXIDANTS AND FREE RADICAL DAMAGE

Free radical reactions are ubiquitous *in vivo*. They are associated with oxidation-reduction reactions, energy metabolism, biosynthesis, cell signaling, body defense, and detoxification mechanisms. Because of potential adverse effects of oxygen and related oxygen products, cell systems utilize numerous defensive mechanisms. These systems include direct interaction with reducing agents (e.g., vitamin C, glutathione); free radical scavenging (vitamin E, vitamin C, carotenoids, superoxide dismutase); reduction of hydroperoxides (e.g., glutathione peroxidase, catalase); removal of transition metals by protein binding (e.g., ferritin, ceruloplasmin, and other chelators); preventing reactive oxygen from reaching specific sites; and even repair of oxidative damage.[2]

There is considerable interest in the function and metabolism of antioxidants and their ability to scavenge free radicals. The generation of free radicals and its related oxidative damage appears to be a consequence of stress, various diseases, aging, trauma, environmental factors such as cigarette smoke or air pollution, infectious organisms, and other factors. As a by-product of oxidative metabolism, the generation of free radicals can probably not be halted entirely but only moderated. Consequently there is a need for biologically active antioxidants and associated scavenger mechanisms. Because free radicals arising from metabolism or environmental sources interact continuously in biologic systems, the oxidants and antioxidants are in a continual “utilization and replenishment” cycle that must be balanced to minimize cellular and tissue damage.

One of the most well-studied systems of biologic oxidative processes has been the effect of free radicals on lipid peroxidation in both cell free and biologic systems. The mechanism of lipid peroxidation consists of three stages: initiation, progression, and termination (Figure 141-1).[3,4] Initiation of lipid peroxidation occurs by abstracting a hydrogen atom from a methylene group, such as exists on an unsaturated fatty acid, by a free radical species. The resulting molecule is now a free radical, which can react rapidly with molecular oxygen to form a peroxy radical. The peroxy radical then abstracts another hydrogen atom from another unsaturated fatty acid to form another free radical species. Because a new free radical is formed, a chain reaction is created resulting in many free radicals being formed from one event. This chain reaction can be terminated when the chain-propagating species reacts

with an antioxidant molecule to form non–free radical products. In the meantime, left to propagate, many highly reactive free radical species are formed. Evidence of this process exists in the numerous molecular markers of tissue destruction that form, such as lipofuscin pigments, iosprostanes, carbonyl and nitrotyrosine protein derivatives, and DNA fragments. Antioxidants thus have the potential to terminate these chain reactions prior to their generating a large degree of cellular damage and hence provide cells the opportunity to complete their individual life cycles.

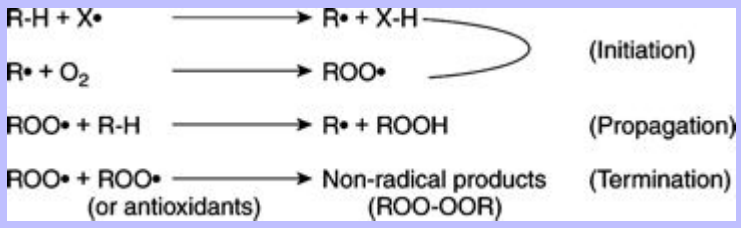
There are a number of biologic and dietary types of antioxidants. These include various tocopherols (vitamin E), vitamin C, beta-carotene, and the enzyme superoxide disumutase. Among these free radical scavengers, vitamin E is often promoted as a diet supplement or food ingredient. Vitamin E is a fat-soluble vitamin and is absorbed from the intestine into the lymph system on lipoproteins. It is then transported to the liver for utilization or storage. Compared with other fat-soluble vitamins (A, D, and K), vitamin E is not efficiently stored.

141.1.1 Vitamin E

Vitamin E is the major lipid-soluble antioxidant present in plasma, erythrocytes, and tissues. The term *vitamin E* actually refers to a group of fat-soluble compounds known as the tocopherols. α-tocopherol is generally regarded as having the greatest antioxidant activity. Its function as a scavenger of free radicals serves to prevent free radical or oxidative damage to polyunsaturated fatty acids in membranes, thiol-rich proteins of membranes, and nucleic acids. Support for an antioxidant role of vitamin E *in vivo* also comes from observations that synthetic antioxidants can either prevent or alleviate certain clinical signs of vitamin E deficiency. Numerous studies have established vitamin E as an essential nutrient.[5,6] Vitamin E has beneficial effects on the canine immune system and a prolonged dietary deficiency of vitamin E will cause oxidative damage and degeneration of the retina of the eye, and lead to reduced visual acuity.[7–13]

522 523

Figure 141-1 Model of fatty acid oxidation by a free-radical mechanism. R-H represents a fatty acid; XX, a free radical capable of abstracting a hydrogen from R-H; RX, a free radical of the fatty acid; ROOX, the peroxy radical; ROOH, a lipid hydroperoxide.



141.1.2 Antioxidant Combination

Vitamin E and other supplementary antioxidants are readily available as commercially manufactured over-the-counter products. Their use as individual dietary supplements is not widespread in veterinary practice. Instead, antioxidant combinations are often incorporated into pet food or supplements are formulated to contain one of more of these substances. One such combination included vitamin E, vitamin C, α-lipoic acid, L-carnitine, and fruit and vegetable-based ingredients that contain flavonoids and carotenoids in a pet food. A study utilizing this food noted that some age-dependent cognitive deficits of dogs were improved.[14] Another

report of using combinations of vitamin E, C and beta-carotene resulted in increased serum vitamin E concentrations and suppressed serum biomarkers of lipid peroxidation (i.e., total serum alkenyls) in dogs and cats. Diet supplementation of sled dogs with beta-carotene, lutein, and vitamin E "normalized" adverse effects of exercise on immune status.[16]

One bioflavonoid blend was fed to cats before administration of acetaminophen and was found to provide some protection against Heinz body formation. Methemoglobinemia formation was not prevented[17]. When cats were pretreated with vitamin E, vitamin C, or N-acetylcysteine, no beneficial effect on Heinz body formation induced with onion powder was seen. However, admininstration of N-acetylcysteine was associated with higher relative amounts of reduced glutathione concentrations in whole blood[18]. When propylene glycol was used to induce Heinz body formation, again only N-acetylcysteine showed a significant effect.

141.1.3 Antioxidants and High-Fat Diets

Is there need for additional dietary antioxidants when higher amounts of polyunsaturated fatty acids are present in the diet? The prevailing opinion is that more vitamin E, particularly α-tocopherol, should be consumed. In humans, when the dietary polyunsaturated fatty acid is linoleic acid, a ratio of 0.4 mg α-tocopherol to 1.0 g polyunsaturated fatty acid is considered appropriate.[19] However, studies to support the need for increased intakes of vitamin E when diets are enriched with longer chain omega-3 fatty acids are equivocal.[20] However, in dogs, when diet intake of vitamin E is high, plasma content on a volume basis was lower in a fish oil supplemented group but it was equivalent when expressed on a plasma lipid basis.[21] In humans plasma tocopherol concentrations either increased (volume basis) or did not change.[20] Thus the results appear to depend upon how the data are expressed, the measures of peroxidation used or the tissues studied. Based on this single study using dogs, it would appear that dietary vitamin E content should be increased when diets high in polyunsaturated fat are employed.

141.1.4 Other Antioxidants

141.1.4.1 Trace Minerals (a Supporting Role)

Trace minerals may be incorporated into antioxidant enzyme proteins. Their adequate provision should help ensure synthesis and activity of these enzyme-based antioxidant systems. These include selenium in glutathione peroxidase, iron in catalase and copper, zinc, or manganese dependent superoxide dismutases. Other antioxidants, such as ceruloplasmin and ferritin, are nonenzymatic antioxidants containing copper and iron, respectively. Assuming that ample dietary quantities of these minerals are present, direct supplementation of these compounds is not required.

141.1.4.2 Vitamin C

Vitamin C can be synthesized by both dogs and cats, and hence is not considered a dietary essential. Nonetheless in response to stress, dietary supplementation may be beneficial.[22,23] Vitamin C may also help prevent oxidative damage induced by onion powder or propylene glycol ingestion in cats.[24] Studies in other species have shown beneficial effects to immune function.

141.1.4.3 Carotenoids

Beta-carotene and other plant-derived substances (lycopene) may provide antioxidant activities in dogs and cats. In dogs, beta-carotene is a precursor of vitamin A, but this pathway is nonfunctional in cats. These materials may also have antioxidant properties, although beta-carotene has been shown to act as a pro-oxidant if large quantities are consumed. Several clinical trials in humans have been terminated because of negative side effects associated with supplementation. These results call for their cautious use in dogs and cats until their safety and efficacy has been established.

141.1.4.4 S-adenosyl-methionine (SAMe)

This compound is synthesized in animals derived from methione in conjunction with adenosine tripohosphate. It is involved in various biochemical and cellular reactions and is a precursor to glutathione via the so-called *transsulfuration pathway*. This pathway is important not only for detoxification reactions but also helps protect against cellular oxidation. In the absence of SAMe, oxidative damage and toxin retention occurs, which presumably contributes to cell injury and disease progression. It has been studied to some extent in dogs and cats and has shown promise in support of liver function in dogs with vacuolar hepatopathy.[24] It has also been evaluated in normal adult cats and appears to be safe at the dosages employed.[24] Its use in clinical cases of liver insult or injury in cats and dogs appears to be increasing although further controlled case studies are warranted.

141.1.4.5 α-Lipoic Acid

This compound is also involved in modifcation of the relative distribution of reduced versus oxidized glutathione and, as such, provides a protective effect against oxidative injury. α-lipoic acid is similar in structure to octanoic acid (an 8-carbon medium chain fatty acid) and can participate in oxidation-reduction reactions, which are fundamental to numerous antioxidant mechanisms. Administration of α-lipoic acid to dogs over a 6-month period was found to increase the reduced versus oxidized glutathione ratios.[25] A dose-dependent response was not observed because the lowest supplement group resulted in the most significant increase. This finding suggests that a narrow dosage range may exist to achieve the desired effect. Also cats reportedly have a decreased capacity to metabolize α-lipoic acid compared with dogs[26] for which some caution is advised regarding its use in this species.

142 CHAPTER • 142 Herbal Medicine

Rebecca L. Remillard

Susan G. Wynn

Until the twentieth century, most remedies were botanicals found by trial and error at a great human cost. Some remedies were harmful and some even deadly. With advancements in pharmacologic methods of isolation and purification, active ingredients were identified, characterized, quantified, and sold as prescription or over-the-counter drugs. More recently, the use of botanical medications has become increasingly popular (approximately $5 billion per year industry in the United States). The use of herbal medicine by veterinarians has been increasing for the last 30 to 40 years.

The growing use of herbal remedies in the United States has far exceeded the available information on their benefits, adverse effects, and drug interactions. A coherent, easily accessible database (human or animal) on such remedies is still nonexistent. FDA's Center for Veterinary Medicine is concerned about these products because they lack scientific data showing safety, efficacy, or even standard good manufacturing practices.[1–3]

These animal herbal products are believed by many to be sold under the Dietary Supplement Health and Education Act (DSHEA) passed by Congress in 1994 because they contain human dietary ingredients. Under DSHEA, FDA regulation is not required and hence most of these products do not have pre-market approval. However, the FDA contends that DSHEA does not apply to animals, and this position has been upheld in at least one court case. Therefore most of the herbal products currently on the market would be considered *unapproved* animal drugs or food additives for animals. Although these products are technically in violation of the law, they are of low enforcement priority except when there are public or animal health concerns.[4]

There are published case reports of people suffering from lead poisoning, renal failure, CNS disorders, and digitalis toxicity linked directly to their herbal medications. Some people have exclusively embraced alternative therapies while refusing known effective conventional therapies.[1,5] Analogous cases are most likely occurring within the field of the veterinary medicine when owners choose to diagnose and treat their pet's medical condition concurrent with or without a veterinarian. Clearly it has been a “buyer beware” market under DSHEA. Late in 2002, the FDA announced a new initiative encouraging companies to make accurate product health claims and to prevent companies from making bogus claims. Dietary supplement companies will have to show “the weight of scientific evidence” supports their product health claims; however, this initiative did not address the issue of product safety.

“It is time for the scientific community to stop giving alternative medicine a free ride. There cannot be two kinds of medicine: a medicine that works and one that may or may not work.” This statement appeared in the *New England Journal of Medicine* in 1998.[5] It would appear that, although herbal medicine has been in use for centuries, the time has come for such remedies to be tested by scientific method. The scientific method is the process by which scientists, collectively, over time, construct an accurate, reliable, consistent, and nonarbitrary representation of the world (Box 142-1). Recognizing that personal and cultural beliefs influence perceptions and interpretations of natural phenomena, through the use of standardized procedures and criteria to minimize those influences, theories are developed. There are pseudo-scientific theories that wrap themselves in a mantle of apparent “experimental” evidence but, when examined closely, they are found to be statements of faith, hearsay, testimonial, or worse, fraud.[6]

The scientific method distinguishes science from other forms of explanation because it requires systematic experimentation. Where there is active study and open communication, the biases of individuals or groups will cancel

out because different groups, with different biases and sources of systematic error, repeat similar experiments. A consensus and theory will develop based upon those experimental results that have stood the test of time. Why has the herbal industry not yet chosen to demonstrate product safety and efficacy using the scientific method?

142.1 HERBAL POLYPHARMACY

The term *drug* comes from the ancient word for "root." Until the 1930s plant drugs were the primary source of medicines.[7] Plants may contain thousands of chemical constituents. Phytochemicals are nonnutritive plant constituents that contain protective, disease-preventing compounds, and more than 900 have been identified as components of food. Some constituents are pharmacologically unique and have been isolated by the drug industry, but other constituents have important activity as well.

Investigating the efficacy of herbal therapies is complicated by these mixtures of compounds, some of which exist in varied forms. Constituents isolated from herbs and tested may have important pharmacologic activity, but data from an isolate may under-or overstate actions of the parent herb. The other "minor" constituents may modify the activity of the primary active constituent, either synergistically or antagonistically. For instance, foxglove is less toxic than its active ingredient digoxin because other plant constituents, some of which antagonize, modulate the actions of digoxin.

525

142.1.1 Box • 142-1 The Scientific Method—a Simple Version[6]

1. Observe some aspect of the universe.
2. Invent a tentative description—hypothesize.
3. Use the hypothesis to make predictions.
4. Test those predictions by experiments or further observations and modify the hypothesis in the light of your results.

Repeat steps 3 and 4 until there are no discrepancies between hypothesis and the experiment results and/or observation. When consistency is obtained, the hypothesis becomes a theory and provides a coherent set of propositions that explain a class of phenomena. A theory is then a framework within which observations are explained and predictions are made.

Quality control problems in the production of herbal medicine exist on several levels. First, plant constituents vary naturally according to climate, culture conditions, and time of year. William Withering, in his famous Account of Foxglove, noted that some patients got minimal results with what he considered to be an overdose and discovered that the only time to gather foxglove leaves for consistent clinical results was while the plant was in early flower.[8]

Manufacturing practices lend a second level of variability to the product. This is due to (1) the use of different (sub-) species and proper identification of the plant; (2) the use of different parts of the plant (herb, roots, leaves, or combination); (3) different methods of extraction (pressed juice, alcoholic extraction); and (4) the variable presence or absence of other plant constituents. An herbal product may contain highly variable amounts of a variety of bioactive ingredients depending on these factors. Herbalists use products usually from one or two manufacturers and continue to do so after becoming comfortable with the potency of those particular products. Some practitioners have found standardized extracts helpful. For a particular medicinal plant, one active

constituent is chosen for standardization and that constituent is concentrated to a predetermined level. A "standardized extract" product ensures that the product has one active constituent at a certain known concentration. However, standardized extracts rely on an admittedly incomplete knowledge of the remaining constituents extracted from that plant.

It has been said that herbal remedies cannot be patented and manufacturers do not expect to recoup the estimated $350 million to confirm FDA safety and efficacy studies.[9] Without patent protection, pharmaceutical companies have not provided financial support for herbal medicine research. The National Institutes of Health since 1992 have only been able to offer limited funding. The lack of regulation on quality control and product standardization for active ingredients that may vary 200-fold between different manufacturers, and batches make it difficult to establish safe or reasonable starting dosages in clinical research protocols.

It would appear that the greatest advantage of herbal medicine, polypharmacy, is at this time its greatest downfall to progress. Polypharmacy, use of multiple drugs with similar, synergistic, or complementary actions, in some respects is discouraged in veterinary medicine. The "shotgun" approach may alleviate clinical signs in the short term but does not increase general medical knowledge, and inadvertently, there may be adverse effects long term. In reality, many practitioners find the use of multiple drugs necessary most commonly in geriatric patients or those with complicated medical problems. At other times, animals are treated with use of multiple drug combinations as in antibiotics, antiparasitic control, vaccines, and anesthesia. Similarly, an herbal formula may contain an astringent (blackberry leaf), soluble fiber (slippery elm), and an antimicrobial (barberry) for treating diarrhea, and the adverse effects of each may be mitigated while addressing several therapeutic principles. Herbal polypharmacy offers the same advantages of efficacy while using lower dosages of the individual active ingredients.

In herbal medicine, polypharmacy is befitting. There are two basic functions performed with herbal medicines: (1) elimination and detoxification and (2) health building and management. The individualized polypharmaceutical approach of herbal medicine is intuitively sensible when encountering a complex, chronic, and often recalcitrant inflammatory process, in which it is advantageous to attack several aspects of the disease process simultaneously. Herbal practitioners create many different formulas for different types of applications. The formulation is contingent on the circumstances, condition being treated, type or part of the plant used, and the characteristics of the patient. For example, in treating lupus erythematosus, one patient may be prescribed a formula designed to relieve joint inflammation and glomerulonephritis, whereas herbs against pleuritis and polyarthropathy are prescribed for another. Herbalists attempt to anticipate and manage associated problems and possible side effects of treatments proactively. The treatment concept is not simply to suppress a symptom but optimize function in a variety of systems while symptoms are resolved.

142.2 EVIDENCE-BASED APPROACH TO HERBAL MEDICINE

There are appropriately designed clinical studies that assess herbal medicinals in reputable human medical journals, which serve well as examples for veterinary researchers.[10–12] There are substantive veterinary studies in the current scientific literature to help elucidate the effects of herbal constituents mostly in dogs, rarely cats:

- A triple antibiotic ointment and an aloe vera extract gel were evaluated as to their effects on open wound healing of pad wounds in dogs. The primary difference between the two medications was noticed at 7 days when the aloe vera extract gel–treated wounds had a smaller unhealed wound area than did control wounds and wounds treated with triple antibiotic ointment (author abstract).[13]

- The effects of garlic (*Allium sativum* L., Liliaceae) dialysate were studied on arrhythmias induced in anesthetized dogs. Garlic dialysate suppressed premature ventricular contractions and ventricular tachycardia in ouabain-intoxicated dogs (abbrev author abstract).[14]

- Effect of [3] ginger (*Zingiber officinale* Roscoe, Zingiberaceae) extracts (acetone, 50% ethanolic and aqueous) was investigated for antiemetic activity induced by 3 mg/kg cisplatin in healthy mongrel dogs. The acetone and 50% ethanolic extract at the doses of 25, 50, 100, and 200 mg/kg per os exhibited significant protection, whereas aqueous extract at these doses was ineffective against cisplatin-induced emesis (abbrev author abstract).[15]

- To determine the effect of a fraction of licorice extract, FM100, on the endogenous release of secretin and exocrine pancreatic secretion, five dogs were prepared with chronic pancreatic fistulas and gastric cannulas. Intraduodenal administration of licorice extract in three different doses (0.5, 1.0, and 2.0 g) resulted in significant increases of both plasma secretin concentrations and pancreatic bicarbonate secretion in a dose-related manner (abbrev author abstract).[16]

- A single oral dose of the lyophilized deathcap fungus *Amanita phalloides* (85 mg/kg BW) caused gastrointestinal signs of diarrhea, retching, vomiting, and death in beagles. Silibinin (milk thistle) administration (50 mg/kg) 5 and 24 hours after intoxication suppressed the serum biochemical changes and markedly reduced the hemorrhagic hepatic necrosis. All silibinin-treated dogs survived (abbrev author abstract).[17]

- Groups of greyhounds and domestic cats infested with *Ctenocephalides felis* were sprayed once with azadirachtin (neem seed extract) with or without diethyltoluamide (Deet) and/or citronella. The results show that methanolic extracts with 200, 1000, or 2400 ppm azadirachtin reduced fleas in a dose-dependent manner in fleacontaminated environments (abbrev author abstract).[18]

- Treatment with an extract of Saw Palmetto (*Serenoa repens*) for 91 days did not significantly affect the prostate gland of asymptomatic dogs, and no adverse effects were evident. Although products containing extracts of S repens are widely advertised for men with prostatic hyperplasia, beneficial or harmful effects of this plant extract were not found in dogs with prostatic hyperplasia (author conclusion).[19]

525

526

- In an open multi-center study, the efficacy and safety of a standardized 10% tea tree oil cream (Bogaskin) applied thinly and twice daily for 4 weeks was tested in 53 dogs with chronic dermatitis, particularly nonspecific eczema, allergic dermatitis, interdigital pyoderma, acral lick dermatitis, and skinfold pyoderma. Efficacy assessed by investigating veterinarians showed a positive response ($p = 0.05$) to treatment in 82% of the dogs (abbrev author abstract).[20]

142.3 HERB TOXICITY

There are reports of medicinal herb toxicity in dogs and cats, although traditional herbal medicine is usually presented with the assumption that humans are the target species (Box 142-2). It is well to remember that herbal drugs should be given the same considerations as when using conventional human pharmaceuticals in dogs and cats. Tea tree oil should only be used topically and never as an oral medication. Comfrey, garlic, and ma huang (ephedra) have documented toxicities and should be used orally only with care and diligent monitoring.[21,22]

Cats present a particularly difficult problem with use of compounds that have not been well studied in felines. Cats have anomalous receptor responses to a number of drugs (e.g., narcotics), are particularly susceptible to phenols, have decreased UDP-glucuronyl transferase activity and increased transaminase and deaminase activities, which makes dosing even more tenuous than in dogs, and hemoglobin that is particularly susceptible to oxidation. Cats have known sensitivities to coumarins, salicylates, and essential oils (aromatherapy included). Herbs of concern in cats may include white willow, birch, garlic, chamomile, and essential oils such as tea tree, pennyroyal, thyme, and eucalyptus.

Dogs are generally more tolerant of xenobiotics but there are documented toxicities to d-limonene, hops, and pennyroyal.[23,24] These should not be used unless under the guidance of an experienced veterinary herbalist, if at all. Onions and garlic (*Allium* sp.) can cause intravascular hemolysis with Heinz bodies, hemoglobinemia, hemoglobinuria, anisocytosis, poikilocytosis, reticulocytosis, and anemia.[25–27] The most common cause of Heinz body hemolysis in dogs is related to ingestion of onions (raw, cooked, or dehydrated). The hemolytic episode may be difficult to correlate with onion ingestion because it occurs several days later.[28]

142.3.1 142.3.1 Box • 142-2 Known Herb Toxicities in Dogs and Cats[24]

Ma Huang	Dogs: CNS and CV sympathetic signs
Guarana	Dogs: caffeine signs
5-HTP (Griffonia)	Dogs: GI and CNS—serotonin syndrome
Echinacea	Dogs: GI, lethargy
Valerian	Dogs and cats: lethargy
Chamomile	Cats: GI, lethargy, epistaxis
St. John's wort	Dogs: GI, depression
Garlic	Dogs and cats: Heinz body anemia, GI
Essential oils	Dogs and cats: CNS, contact dermatitis, liver
Hops	Dogs: malignant hyperthermia

142.4 HERB-DRUG INTERACTIONS

In clinical practice, polypharmacy is not uncommon, particularly if the owner uses the services from several veterinary practices. Many medicinal herbs and conventional drugs are therapeutic at one dose and toxic at another. Interactions between herbs and drugs may increase or decrease the pharmacologic or toxicologic effects of other.[29] Underreporting of drug interactions in conventional medicine is a major problem that may be more so for herb-drug or herb-herb interactions as herbs are considered “natural and therefore harmless” by the general public. However, in several large hospital studies completed in Taiwan, Philippines, Hong Kong, United Kingdom, and by the World Health Organization Collaborating Center for International Drug Monitoring, herb-drug interactions were documented in 0.2% to 25% of cases, depending on survey design.[30]

Anesthesiologists have reported significant changes in heart rate or blood pressure in human patients taking herbal medications such as St. John's wort, gingko biloba, and ginseng. Research is ongoing to determine how certain herbals interact with certain anesthetics and in general, the findings thus far indicate that certain herbal medicines do prolong the effects of anesthesia and increase the risks of bleeding or raise blood pressure.[7] Herbal medicines significantly affect the cardiovascular system and many herbal preparations have multiple cardiovascular effects, which can be additive. In general, the dilution of active components in herbal medicines results in fewer adverse and toxic effects as compared with the active components in pharmaceuticals; however, these interactions should not be overlooked for the overall well-being of the patient.[31]

One of the best overall reviews completed to date discusses herbal-drug interactions from both the herbal and conventional medicinal perspectives using *in vivo, in vitro,* case reports, and clinical (animal and human) studies citing dosages and statistically significance when available.[32,33] Herb and drug interactions should also be researched.[34,35] The German Ministry of Health established the Commission E, a committee of doctors, pharmacists, scientists, and herbalists to evaluate the safety, quality, and efficacy of herbs. The monographs contain recommendations on dose, indications, contraindications, interactions, and mechanisms of action.[36] The chemical composition, pharmacologic action, toxicity, and therapeutic value of more than 400 herbs with correlations between Western pharmacology and the teachings of traditional Chinese medicine for pharmacologists, physicians, and toxicologists can be found in Huang.[37]

In summary, the individualized polypharmaceutical approach of herbal medicine would appear appropriate and not particularly out of the ordinary for veterinary medicine. Although, this approach does make scientific analysis more challenging, the time has come for such analysis; it will be necessary for herbs to gain greater acceptance and widespread use. A systematic analysis and clinical testing of herbal remedies is feasible. Food may serve as a worthy example. Like herbal remedies, foods are not made up of just one nutrient, and their chemical composition is highly variable for the same reasons as herbs. Foods and nutritional supplements also cannot be patented as single ingredients, but specific unique combinations thereof can be reliably produced, researched, and marketed (e.g., Cosequin).[*†] Veterinary herbalists would do well to proactively develop a standard for some therapeutic herbs, consistently produce and document reliable efficacy, and then participate in the scientific method by publishing their case results.

143 CHAPTER • 143 Adverse Drug Reactions

Jill E. Maddison

Stephen W. Page

Any harmful and undesirable phenomenon that occurs during treatment of a patient is termed an *adverse event* (AE). When drug treatment is associated with an adverse event, it is termed an *adverse drug reaction* (ADR). Although no universally accepted definition exists, most medical and veterinary authorities concur that an ADR is a reaction that is harmful and unintended and occurs at doses normally used for prophylaxis, diagnosis, or treatment of disease or the modification of physiologic function.

All drugs have the potential to result in an ADR. However, because it is frequently difficult to substantiate the cause of an adverse event, it is common to refer to an ADR as a *suspected ADR* (sADR) until a clearer picture of etiology emerges. ADRs present a continuum of clinical significance, but of greatest concern are serious ADRs described as adverse drug reactions that are fatal, life threatening, disabling, or incapacitating or which result in permanent or prolonged adverse clinical signs. Figure 143-1 provides an overview of the rational approach to investigating AEs and ADRs.

If not prevented, ADRs can result in additional treatment costs, ongoing disability, mortality, and the client's loss of trust in and diminished satisfaction with the veterinarian. To maintain the highest standards of care and to ensure that ADRs are not needlessly replicated, it is critical that sADRs be fully investigated. Reports of sADRs to manufacturers, regulatory authorities, and the profession are valuable. They help build a risk profile of the implicated drug and its class, improve the knowledge and therapeutic skills of clinicians, provide pivotal information for pharmacoepidemiologic studies, and assist in clarification of the cause.

143.1 CLASSIFICATION OF ADVERSE DRUG REACTIONS

An alphabetic approach to ADRs has been recommended.[1]

Type A (augmented) ADRs are expected but exaggerated pharmacologic or toxic responses to a drug. They may be an exaggeration of the intended response to the drug, a secondary response affecting an organ other than the target organ but predictable based on the pharmacology of the drug, or at the extreme, a toxic response.

Most ADRs of this type are attributable to differences in drug disposition that result in higher plasma and tissue drug concentrations, which arise from dysfunction of organs of metabolism and excretion, or inappropriate dosage (e.g., the administration of a non-lipid soluble drug to an obese dog with no dose adjustment). Type A ADRs are usually dose-dependent and avoidable if sufficient drug and animal information is available and considered.

Type B (bizarre) reactions are unexpected or aberrant responses that are unrelated to the drug's pharmacologic effect, are not dose dependent, and are unpredictable (idiosyncratic). Type B ADRs include allergic and pseudoallergic (nonimmunologic) reactions, direct toxic effects on organs that are associated with actions unrelated to any desired therapeutic effect (the mechanisms for which may be complex and obscure), and aberrant responses in different species.

Type C (chronic) ADRs occur during prolonged treatment programs. For example, iatrogenic Cushing's syndrome with chronic use of prednisolone.

Type D (delayed) ADRs are experienced remote from the time of treatment and therefore may be difficult to diagnose in the absence of an astute clinician and an excellent history. Second cancers developing in patients treated with alkylating agents are classical examples, as is human phocomelia after thalidomide administration.

Type E (end of treatment) ADRs occur in specific situations when drug treatment is terminated suddenly; for example, withdrawal seizures manifested on termination anticonvulsant therapy, or adrenocortical insufficiency subsequent to interruption of chronic glucorticoid treatment.

Type F (failure) ADRs occur when the expected response to treatment is not achieved. Although there are myriad examples of clinical failure, critical analysis reveals primary drug failure to be an infrequent principal cause.

Type G (gaffes) ADRs result from human error, either delayed or inaccurate diagnosis, withholding treatment, prescription of an inappropriate drug, administration of an incorrect dosage regimen, or failure to monitor the response to treatment.

143.2 INCIDENCE OF ADVERSE DRUG REACTIONS

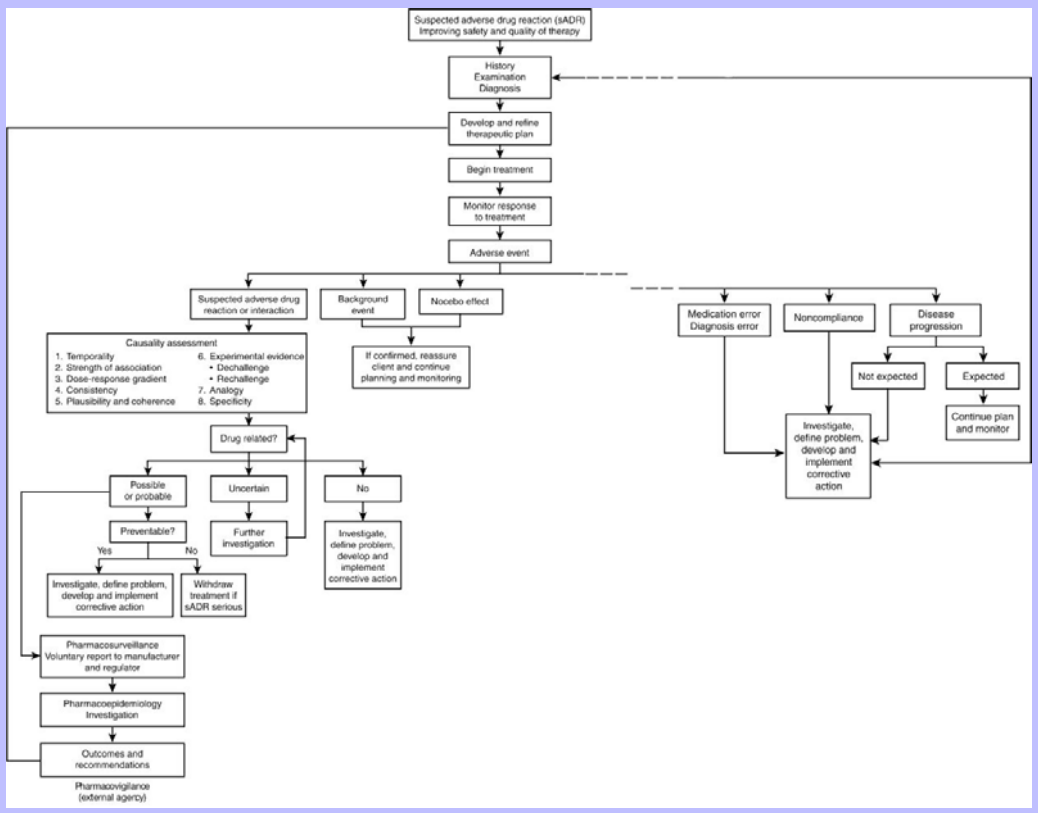
The incidence of ADRs in veterinary medicine is not well known. Studies of human ADRs provide a variety of estimates from 1.5% to 35% of patients developing an ADR while hospitalized.[2] It has been estimated that 1% of the veterinary hospital population treated with drugs experience ADRs but there are divergent opinions between clinicians about the frequency and importance of ADRs.[3] It is certain that ADR reporting rates are low within the medial community and likely substantially lower in veterinary practice.

Furthermore, the occurrence of ADRs is not homogenous throughout any population. Animals with genetic, physiologic, or pathologic predispositions have a higher likelihood of an ADR than those without. Although complacency in reporting is widespread, an examination of those factors associated with an increased rate of reporting reveals that the likelihood of reporting is related to the novelty of the reaction, severity of the reaction, limited time of suspected drug on the market, media coverage, and the litigiousness of the owner.

143.3 DIFFICULTIES IN DIAGNOSIS OF ADVERSE DRUG REACTIONS

One problem in determination of the incidence of ADRs is difficulty in diagnosis. Appropriate ADR diagnosis is heavily dependent on the expertise of the clinician and the quality of the information available. Even experienced clinicians have difficulty in determining causality, and experts disagree more than 50% of the time when assigning causality to an ADR.

Figure 143-1 Algorithm for adverse drug reactions.



The clinical signs of an ADR are almost always nonspecific and rarely pathognomonic. In humans, the most common symptoms of ADRs (e.g., nausea/vomiting, diarrhea, abdominal pain, rash, pruritis, drowsiness, headache) are also reported in 80% of healthy patients who receive no medication.[2] Placebo administration increases the percentage of patients with symptoms and the number of symptoms per patient.[2] Adverse reactions occurring in response to administration of a placebo are termed *nocebo effects* (from the Latin root that gives rise to noxious and nociception, and which translates as "I will harm").[4] During the clinical field study to substantiate the benefits of carprofen[5] and etodolac,[6] a variety of adverse reactions were reported in dogs that received the placebo formulation, including inappetence (1.6% of dogs), vomiting (2.4%), regurgitation (2.6%), lethargy (2.6%), and diarrhea/soft stools (2.4%). Of the full complement of ADRs that occurred in response to active treatment, a fraction were due to the nocebo phenomenon, and another fraction reflected the background frequency of adverse signs in the untreated population. As veterinarians are reliant on the observations of owners who are potentially subject to various conscious and subconscious influences associated with expectation, suggestion, and prior conditioning, nocebo effects are likely to contribute to reports of ADRs. Complicating ADR identification further is the possible impact of the nocebo phenomenon that influences client compliance.

Other factors that hinder the diagnosis of a true ADR include multiple medications, underlying pathology, and the assumption that the active principle of a medication is responsible for the ADR. Reactions may be due to excipients or may arise in response to degradation products formed during product storage.

143.4 IDENTIFICATION OF ADVERSE DRUG REACTIONS

The likelihood, frequency, and severity of ADRs are dependent on the interaction of drug, animal, disease, and client factors. Table 143-1 provides information that should allow the risk of ADRs to be reduced in animals with compromised renal or hepatic function. Table 143-2 identifies drugs not recommended for use in cats. Justification for selection of any drug includes the favorable ratio of anticipated benefits versus potential risks. In life-threatening situations, use of a drug with a narrow therapeutic ratio may be warranted, whereas the use of a drug with a narrow therapeutic ratio to treat trivial problems has little merit.

Accurate identification of an ADR may go undetected if the clinical signs are indistinguishable from those shared with common disease syndromes, including the disease being treated. Clinicians must always be alert to the possibility that abnormalities developed during the course of an illness may be due to the treatment rather than to the disease process itself.

Assessment of causality of an ADR can also pose a significant challenge. Figure 143-1 summarizes eight major steps in the process of attribution of cause. These steps are explained in greater detail by Maddison and Page[7] and in clinical epidemiology texts.[8,9] By application of a systematic approach, a critical, objective, and transparent conclusion can be reached, which avoids undue influence of intuition, preconception, and suggestion.

In many situations, it is not possible to judge an individual case and further information and cases must be sought. 530
The potential value of post-marketing pharmacovigilance programs conducted by many national regulatory agencies can be realized only if clinicians submit details of sADR. Important benefits include identification of preventable ADRs, discovery of trends and clusters of significant ADRs, assessment of the safety of drug regimens, measurement of ADR incidence (only if information on drug use is available), and identification of patient risk factors. Clinician-driven ADR reports potentially signal need for further investigations. 531

Table • 143-1 Examples of Drugs That Should Be Avoided or Used with Caution in Animals with Hepatic or Renal Disease

DRUG CLASS	SPECIAL CONSIDERATION IN PATIENTS WITH LIVER DISEASE	SPECIAL CONSIDERATION IN PATIENTS WITH RENAL DISEASE
Antimicrobial drugs	Chloramphenicol	Aminoglycosides*‡
	Chlortetracycline*	Amphotericin*‡
	Erythromycin estolate*	Fluoroquinolones
	Flucytosine	Lincomycin
	Griseofulvin	Naficillin
	Ketoconazole	Nalidixic acid
	Lincosamides	Nitrofurantoin
	Macrolides	Polymyxins
	Metronidazole	Sulphonamide-trimethroprim
	Sulphonamide-trimethoprim*†	Sulphonamides
	Sulphonamides	Tetracyclines (except doxycycline)
	Tetracyclines	
Anesthetics/sedatives/anticonvulsants	Anticonvulsants	Acepromazine
	Barbiturates*‡	Chlorpromazine
	Chlorpromazine	Ketamine
	Diazepam‡	Methoxyflurane*‡
	Halogenated anesthetics	Procainamide
	Ketamine	
	Lignocaine	
	Propofol	
Cardiac drugs	Beta blockers	Angiotensin-converting enzyme inhibitors
	Lignocaine	
	Quinidine	
		Cardiac glycosides
		Procainamide
Diuretics		Spironolactone
		Thiazides
Anti-inflammato-ries and analgesics	Butorphanol	Nonsteroidal anti-inflammatorydrugs*‡
	Corticosteroids	Meperidine(pethidine)
	Meclofenamic acid	Polysulfatedglycosamino-glycan
	Phenylbutazone	
	Polysulfated glycosamino-glycan	
Cytotoxic drugs	Doxorubicin	Cisplatin*
		Doxorubicin*‡
		Fluorouracil

		Methotrexate*‡
Miscellaneous	Doxapram	Allopurinol
	Heparin	Doxapram
	Suxamethonium	Gallamine
		Piperazine

* Avoid.

† Hepatoxic or hepatotoxic.

‡ Nephrotoxic.

Table • 143-2 Drugs Not Recommended for Use in Cats

DRUG	EFFECT
Acetominophen (paracetamol)	Methemoglobinemia and Heinz body anemia
Apomorphine	Significant CNS depression
Azathioprine	Bone marrow suppression
Benzocaine	Methemoglobinemia
	Laryngeal edema
Cisplatin	Fatal, acute pulmonary edema
Hexachlorophene (found in surgical scrubs, enemas)	Vomiting
	Depression
	Ataxia
	Paralysis
Permethrin	Seizures
	Hyperesthesia
	Tremor and muscle fasciculation
Primidone	Efficacy as anticonvulsant due to poor conversion to pheno-barbitone questionable and high incidence of toxicity
Propylthiouracil	Lethargy
	Weakness
	Anorexia
	Bleeding diathesis
Phenytoin	Sedation
	Ataxia
	Anorexia
	Dermal atrophy
Scopolamine	Tendency to cause behavioral changes
Sodium phosphate enemas	Depression
	Ataxia
	Vomiting
	Bloody diarrhea
Thiacetarsamide	Drug fever
	Respiratory distress
	Fulminant pulmonary edema

Greatest clinical benefit arises from focus on those signals meeting the **SNIP** criteria[10]: **S**trength of the signal (number of reports and their plausibility); **N**ew and unexpected ADRs; **I**mportance of the ADR clinically as judged by severity and seriousness; and **P**reventative potential of various interventions. At the time a new drug is first introduced, only an incomplete description of its adverse reaction profile is available due to the limited numbers of animals included in clinical studies, the short duration of most studies, and the relatively narrow population base studied. Only when used in large numbers in a heterogenous population can infrequent adverse

reactions be identified and risk factors characterized, highlighting the clinical importance of continued pharmacovigilance.

143.5 FACTORS THAT INFLUENCE TYPE A ADVERSE DRUG REACTIONS

It is important to understand the factors that modify the effects of drugs and their dosage to anticipate when a patient may be at increased risk of a Type A ADR. The potential for a Type A ADR is higher in animals with organ dysfunction (see Table 143-1), particularly renal, hepatic, or cardiac dysfunction; in very young or very old animals; in animals to whom a number of drugs are administered concurrently (potentially including all non-prescribed medications); in species for which safe use of the drug or class of drugs has not been established (see Tables 143-2 and 143-3 in relation to cats) and in obese or cachectic patients. In general, type A ADRs should be avoidable if the above factors are considered and dosage regimens are altered appropriately. The reader is referred to other sources for a more complete discussion of these factors.[3,7,11]

143.6 TYPE B ADVERSE DRUG REACTIONS (HYPERSENSITIVITY)

Type B ADRs are unrelated to dose, hard to predict, and difficult to avoid. The major example of these idiosyncratic ADRs are allergic or hypersensitivity reactions. Drug hypersensitivity reactions are more common in patients with a prior history of allergic reactions to the drug or atopic patients. However, they can occur in any individual.

Allergic drug reactions may occur as a result of a number of different immunologic mechanisms, including immediate hypersensitivity (Type I), cytotoxic hypersensitivity (Type II), immune complex formation (Type III), and delayed hypersensitivity (Type IV). However, the pathophysiology of many drug reactions eludes precise characterization and some immune reactions are a result of a combination of mechanisms.

Relatively few drugs are responsible for inducing allergic drug reactions as most drugs are not capable of covalently bonding with proteins, a requisite step to render a molecule immunogenic. The drug/drug metabolite-protein complex must have multiple antigenic combining sites to stimulate a drug-specific immune response and to elicit an allergic reaction. For those drugs that are capable of inducing an immunologic response, it is generally the metabolites of the drug that are chemically reactive and easily form covalent bonds with macromolecules.

Drug hypersensitivity may manifest in different ways. Acute anaphylaxis is associated with IgE and mast cell degranulation. It is characterized by one or all of the following clinical signs: hypotension, bronchospasm, angioedema, urticaria, erythema, pruritis, pharyngeal and/or laryngeal edema, vomiting, and colic. The main shock or target organ for anaphylactic reactions varies between species (e.g., hepatic veins are the main target in dogs and the bronchi, bronchioles, and pulmonary vein in cats).

A systemic allergic reaction may also occur associated with drug use related to deposition of immune complexes in tissues and activation of complement. Drug hypersensitivity should be considered in the differential diagnosis of any apparent immune-mediated disease, for example polyarthropathy, hemolytic anemia, and vesicular/ulcerative dermatitis.

Table • 143-3 Therapeutically Useful Drugs in Cats with Different Dose Recommendations or Side Effect Profiles Compared with Dogs

DRUG	EFFECT IN CATS COMPARED WITH DOGS
Aminoglycosides	Cats more sensitive to nephrotoxic and ototoxic effects
Amphotericin	Cats more sensitive to adverse effects including anaphylaxis
Bethanecol	Administer orally only; parenteral administration associated with life-threatening adverse reactions
Carprofen	Chronic use not safe due to long half-life Single use only
Chloramphenicol	Much lower dose than dogs; 50 mg/cat bid versus 50 mg/kg bid in dogs
Digoxin	Cats more sensitive to toxicity; reduce dose and frequency 30 g every other day for cats that weigh less than 3 kg, 30 µg every day for cats that weigh more than 6 kg
Doxorubicin	Renal failure may occur; use lower dose (25 mg/m^2)
Enrofloxacin	Acute blindness reported with (usually but not always) high dose use
Furosemide	More susceptible to dehydration and hypokalemia; use lower end of dose range
Griseofulvin	Bone marrow dyscrasia risk increased in FIV-positive cats
Ketoconazole	Anorexia and GI side effects more common
Lignocaine	Cats more commonly develop seizures with lignocaine and must be used cautiously
Megestrol acetate	Mammary hypertrophy and neoplasia Cystic endometritis and pyometra Diabetes mellitus
Naloxone	Reversal of opioids is unpredictable
Opioids	Inconsistent sedation
Morphine	Increased risk of excitation Use one tenth of dose in dogs Meperidine (pethidine), butorphanol, and buprenorphine are more predictable
Potassium bromide	Shorter half-life than in dogs (mean of 1.56 versus 5.3 weeks) Adverse effects more common in cats than dogs Coughing is common side effect
Salicylates	Aspirin has a longer half-life; dose every 72 hours Use sulphasalazine (reduce dosing frequency) and bismuth salicylate (avoid repeated use) with caution
Tetracyclines	Drug fever

Prior exposure to the drug is not essential, because hypersensitivity may develop within the course of repeated drug administration. For example, in humans, drug hypersensitivity can develop within as little as 5 to 7 days in a patient previously unexposed to the drug.

Allergic drug reactions should be managed by withdrawal from the drug and treatment with corticosteroids if needed. Adrenaline and fluid therapy may be needed to successfully manage acute anaphylactic reactions.

144 CHAPTER • 144 Therapeutic Use of Acupuncture for Pain Control

James S. Gaynor

144.1 INTRODUCTION TO ACUPUNCTURE

Acupuncture is the stimulating of specific anatomic points in the body to produce therapeutic or analgesic effects. Clinicians most frequently perform acupuncture by using a fine-gauge needle to puncture the skin, although heat and pressure may also be used. In the last several decades, acupuncture has received increasing attention in the United States and Western Europe, resulting in training programs for physicians and veterinarians. In addition, increased research funding has allowed investigators to formulate and test hypotheses of physiologic explanations of acupuncture's actions. The results have been promising enough for the National Institutes of Health (NIH) to develop a specific office to organize funding, national research, and workshops centering on acupuncture and other complementary therapies. A recent report from NIH listed several indications for acupuncture, of which pain management was one.[1,2]

144.2 WHAT IS ACUPUNCTURE?

Acupuncture is an ancient form of diagnosing, treating, and preventing disease that recognizes and encourages the body's own healing potential. It involves the insertion of needles, or other forms of stimulation, into acupuncture points that are precisely defined loci just beneath the surface of the body. An acupuncture point can be stimulated in many ways, including dry needling, injection of fluid into the point, low-intensity or “cold” laser stimulation, and manual pressure on the point (acupressure). The effects of stimulating these points may be intensified, or the duration lengthened, by heating or electrically stimulating the needles. The effects of acupuncture may be prolonged by injection of fluid (e.g., physiologic saline or vitamin B_{12}) or implantation of gold beads into the point. Several hundred acupuncture points are recognized; most are located along acupuncture meridians, or channels, each of which have specific locations and functions. In practice, however, an acupuncturist's repertoire of points may only include a fraction of these. Characteristics of acupuncture points and of the tissues between them allow for body-wide transmission and integration of bioelectric, humoral, and nervous information.

144.3 TRADITIONAL CHINESE MEDICAL BASIS OF ACUPUNCTURE

The commonly accepted explanation for the methods of acupuncture can be traced back over 3000 years, when acupuncture became an important part of traditional Chinese medicine (TCM). With limited knowledge of anatomy or physiology, early explanations were metaphysical in nature and based upon numerology and the philosophy of Taoism. Acupuncture served to increase or decrease the flow of energy (Qi) in hypothesized lines or channels called *meridians*. Although meridians have never been demonstrated to exist, meridian theory is widely enunciated as an explanation for many of the practices of TCM.

From a TCM perspective, pain can be a result of an excess condition leading to the obstruction of the circulation of Qi and blood. Pain can also be caused by deficiency conditions, such as deficiency of Qi and blood and consumption of body fluids from *yin* deficiency. These conditions cause malnourishment of the channels and hence pain. Stagnation of Qi causes distension, with distending pain and no fixed location.[3]

The principles behind acupuncture therapy are to restore a balance in the body. Acupuncture needles placed in appropriate locations can help resolve the underlying causes. This ultimately restores Qi and blood circulation to

normal. With no obstruction, no pain is felt.[3] Although some medical professionals may find the concepts of TCM untenable, the physiologic and clinical evidence for acupuncture's usefulness makes it a viable treatment option and prevents it from being cast aside as witchcraft or voodoo.

144.4 PHYSIOLOGIC BASIS FOR THE USE OF ACUPUNCTURE

The effects of acupuncture on the central nervous system (CNS) and peripheral nervous system (PNS) include an activation of the body's endogenous multilevel pain modulatory systems, causing a release of serotonin, opioid substances, and other neurotransmitters, thereby serving to alter nociceptive processing and perception.[4,5] Although in the West, acupuncture is most widely recognized for its analgesic and musculoskeletal effects, signals generated from stimulation of acupuncture points can also affect the viscera, the immune system, and more. How these signals enter the nervous system as a result of acupuncture is well researched, with several proposed mechanisms. It is likely that a combination of all of them is responsible for what is observed clinically.

In 1976, shortly after opiate receptors were discovered in the periaqueductal gray matter, the limbic system, and the periventricular gray matter of the CNS, it was demonstrated that acupuncture analgesia could be reversed by naloxone, a pure antagonist at all known opioid receptors.[4] This led to the first awareness that acupuncture analgesia was likely mediated through a system of endogenous opioids.

Nociceptive information is transmitted in the CNS by neurotransmitters. Changes in cerebrospinal fluid (CSF) concentrations of neurotransmitters such as serotonin and biogenic amines have been shown with acupuncture.[6] Although several neurotransmitters are involved in the transmission, inhibition, and perception of nociceptive information, the opioid peptides (met-enkephalin, leu-enkephalin, beta-endorphin, and dynorphin) have been the most thoroughly studied with respect to the observed systemic and analgesic effects of acupuncture.

These opioid peptides are involved in activation of descending tracts that inhibit transmission of nociceptive information in the spinal cord.[6] In addition, no inhibition of ascending tracts that transmit nociceptive information occurs. When large unmyelinated A delta fibers, which transmit touch and pressure sensation, are stimulated by the insertion of an acupuncture needle, impulses from small unmyelinated C fibers, which transmit ascending nociceptive information, are blocked by a “gate” of inhibitory interneurons in the substantia gelatinosa of the spinal cord, which release neurotransmitters such as gamma-aminobutyric acid (GABA) and enkephalins.[6] This results in inhibition of transmission of pain impulses to the brain for conscious perception. In addition, a regional effect is seen when the A delta fibers transmit both cranially and caudally in the dorsolateral funiculus before entering the substantia gelatinosa to stimulate inhibitory interneurons.[6]

Several different lines of basic research show that some of the effects of acupuncture are at least partially mediated by substances with opiate-like activity. Substances known to block opioid biosynthesis (e.g., cyclohexamide) or action (e.g., naloxone) reduce acupuncture analgesia, whereas peptidase inhibitors such as D-amino acids (e.g., D-phenylalanine) can potentiate and prolong acupuncture analgesia, presumably by inhibiting degradation of the analgesic opioid peptides.[7] Mice deficient in opioid receptors and rats deficient in opioids show poor acupuncture analgesia.[8] Opioid levels rise in the blood and CSF and fall in specific brain regions during acupuncture analgesia.[9] In sum, part of the analgesia obtained from acupuncture involves the activation of a neurohumoral system resulting in the release of endogenous substances with opioid analgesic activity.[10] Naloxone administration does not lower baseline thresholds for pain, indicating that the analgesic effects observed are from acupuncture alone. A differential release of beta-endorphin, met-enkephalin, and dynorphin occurs in response to low-and high-frequency electroacupuncture.[11] Electroacupuncture involves the application of electricity to the needles

during stimulation of a point. Different opioid receptors mediate the analgesia produced by low-and high-frequency acupuncture. The clinical significance of this differential release is that low-frequency 533
electroacupuncture (2 to 15 Hz), which causes the release of beta-endorphin and met-enkephalin in the brain and dynorphin in the spinal cord, seems to alleviate deep and chronic pain more effectively than does higher-frequency stimulation (100 Hz), which causes release of dynorphin. In addition, the effects of acupuncture in the periaqueductal gray matter may be predominantly mediated by the enkephalins and beta-endorphin, whereas spinal cord effects are predominantly dependant upon enkephalins and dynorphin.[12] Overall it is likely that the three types of opioids act synergistically because they preferentially bind their receptors; beta-endorphin and met-enkephalin bind both mu and delta receptors, whereas dynorphin is a relatively specific kappa agonist. Because acupuncture analgesia can be largely blocked by antagonists of any of these receptors, or with the removal or blockage of any of these opioids, it is likely that they have a synergistic relationship with respect to conferring analgesia when they are simultaneously stimulated by acupuncture. The lack of decrease in observed analgesia with vascular occlusion is further evidence indicating that a nonhumoral mechanism (i.e., opioid neurotransmitter activity) is responsible for the analgesic effects of acupuncture. The mechanism may involve a change in the body's bioelectric environment leading to modulation of the endogenous pain inhibitory system via the CNS. It is now accepted that acupuncture analgesia is not just the result of the actions of endogenous opioids, even though much of the research has focused on this aspect. 534

144.5 USES FOR ACUPUNCTURE

Acupuncture has traditionally been used for virtually all of the same medical conditions for which conventional medicine has been used. These areas include (but are not limited to) pain, as well as musculoskeletal, neurologic, dermatologic, cardiovascular, respiratory, gastrointestinal (GI), urogenital, and reproductive disorders. Many of the claims of efficacy are related to anecdotal evidence and are not based on good clinical or laboratory research. There is strong evidence to support the positive effects of acupuncture on a number of problems (e.g., its ability to alleviate pain in humans and animals).

144.6 SPECIFIC TECHNIQUE FOR PROVIDING ACUPUNCTURE ANALGESIA

Multiple principles exist for choosing points to provide analgesia. One principle indicates choosing points in the affected area. Relative to limb pain, other principles describe using an opposite or contralateral limb. This may be especially useful for limbs that have been traumatized and are not accessible due to bandaging or casting. This is also important for patients with cancer-related pain. Acupuncture may be contraindicated at the sight of a tumor because needle placement may increase blood flow to the area. Another concept is to use empiric points that have been demonstrated to provide analgesia in one or more areas. An evolving principle is to use points proximal and distal to the painful area. All of these treatment principles have been combined for the protocols in Table 144-1. Low-frequency (2 to 5 Hz) electrical stimulation (EAP) is recommended when paired points are listed. For most protocols, points are paired on the same meridian, although exceptions exist. For good analgesia, electrical stimulation should last a minimum of 18 to 20 minutes. It is common for an anesthetized patient's heart rate to drop during this time, a probable indication of central endorphin release.

The acupuncture protocols in Table 144-1 are useful for multiple types of pain. Initially, patients with chronic pain will benefit from frequent treatments. For example, a patient with chronic hip dysplasia will typically be treated three times the first week, two times the second week, once the third week, and then intermittently over weeks to months to maintain comfort. Longer duration chronic pain often requires more frequent treatments early on; it is important for the client to understand that multiple treatments may be required before a significant effect is produced. It is usually recommended that clients commit to six to eight acupuncture treatments before making an assessment of its efficacy for chronic pain.

Table • 144-1 Commonly Used Points for Orthopedic Pain

AREA OF PAIN	POINTS TO BE USED
Hip pain	BL 54-BL 40: EAP
	GB 29-GB 30: EAP
	GB 34
	BL 11 bilaterally
Femoral pain	BL 54-BL 40: EAP
	GB 30-GB 34: EAP
	BL 11 bilaterally
Stifle pain	GB 33-GB 34: EAP
	LIV 8-SP 9: EAP
	Xiyan: EAP
Tibia/fibula pain	BL 40-BL 60: EAP
	ST 35-ST 41: EAP
	GB 34-GB 39: EAP
	SP 6-SP 9: EAP
	BL 11 bilaterally
Tarsal pain	BL 40-BL 62: EAP
	SP 3-SP 6: EAP
	ST 41-ST 44: EAP
	BL 60
	KI 3 (may be needled with BL 60)
	BL 11 bilaterally
Shoulder pain	TH 14-LI 15: EAP
	SI 9-SI 11: EAP
	GB 20
	GB 34
Humeral pain	TH 14-TH 5: EAP
	SI 9-SI 3: EAP
	BL 11 bilaterally
Elbow pain	TH 14-TH 3: EAP
	SI 3-SI 8: EAP
	LI 4-LI 15: EAP
	HT 3
	PC 3
	LU 5
	BL 11 bilaterally
Radius/ulna pain	SI 3-SI 9: EAP
	LI 4-LI 15: EAP
	PC 6-PC 3: EAP
	BL 11 bilaterally
Carpal pain	TH 14-TH 3: EAP
	SI 3-SI 8: EAP
	PC 8-PC 6: EAP
	LI 4-LU 7: EAP
	BL 11 bilaterally

EAP, Electrical stimulation:2–5 Hz, alternating current, continuous stimulation for 20 minutes.

534

535

Acupuncture can be used anytime in the perioperative period for cases involving surgical procedures. Protocols may be useful as preemptive analgesia prior to surgery to help decrease the amount of anesthetics necessary and to aid in keeping the patient more comfortable upon awakening. When used postoperatively, it is ideal to provide the acupuncture while the patient is still asleep. This makes needle placement and electrical stimulation very easy without the constraints of a patient who may wake up immediately painful or in anesthetic emergence delirium.

Although electrical stimulation is not necessary, it helps enhance and ensure adequate analgesia that may last hours to days, depending upon the individual and the procedure.

145 CHAPTER • 145 Meeting the Needs of Patient and Client Through Compassionate Care

Gregory K. Ogilvie

Cancer, diabetes, inflammatory bowel disease, osteoarthritis, cognitive dysfunction disorder; these words can be frightening to many pet owners. To our clients and to some crucial members of our veterinary health care teams, these and other terms are as dark and empty as the diseases they represent. Each day we enter our practices to diagnose, treat, and support our patients, but we often forget the emotion and feelings that surround each patient and client. These diagnoses often bring with them feelings of overwhelming fear, a spiraling sense of loss of control, and most devastating of all, the loss of hope. This loss of hope can be paralyzing for clients, for veterinary staff, and for veterinarians. This evaporation of hope and control occurs regardless of whether the patient is a human family member or a precious pet. When clients face many diseases in a beloved pet, it is sometimes even more difficult than if they themselves had these diseases. Clinicians and their clients often feel responsible for making important and life-changing decisions for animals that rely on them for their well-being. These animals not only share our homes, our lives, and our experiences but also our hearts. These "family members" extend unconditional love and attention, and they deserve proper decisions to enhance their quality and dignity of life. Our goal becomes to share as many moments as possible within this wonderful relationship that some term *the human-animal bond*, *the family-pet-veterinary bond*, or just *the bond*.

The purpose of this chapter is to reignite within the reader the very reason why most of us came to this profession: to care for our animal patients not only using our knowledge and skills but also our hearts. The information is not necessarily new, but it is often lost after days and years of busy practice life. These principals reside within every member of the veterinary health care team and are the very reason why the veterinary profession has been revered as one of compassion and caring.

145.1 DISPELLING THE MYTH (STEP 1)

It is important for veterinarians to dispel the myths[1,2] and misperceptions that surround many diseases and their treatments with honest, realistic, balanced information that translates into knowledge. Knowledge of a disease, options for care, and the likely course of the malady displaces fear, restores control, and allows for a more objective decision-making process. Indeed, in most situations, clients should be comforted that after they have considered all the information and options, there may still be no ideal decision for their pets; however, the best decision will be one that works at the particular time with the client's finances, philosophy, and goals for quality of life. The reader should note that dispelling the myths does not suggest "sugar coating" information, but it does suggest providing honest, accurate, realistic, measured, honest hope.

The most obvious example of a disease that is shrouded in myths and misperceptions is the diagnosis of cancer. Most people have an irrational fear of cancer. However, cancer is the most curable of all chronic diseases. Unjustified, ingrained fears about unrealistic cost, toxicity, and the lack of efficacy associated with care blocks many of us from even considering options for the diagnosis and treatment of cancer. Dispelling the myths associated with cancer can empower the medical team and the client to make clear rational decisions considering all the options.

145.1.1 Examples of Action Steps for Dispelling Myths

To dispel myths, clinicians can do the following:

- Lend the client a recording of an actual discussion of disease and treatment.
- Write out “bullet points” of the discussion.
- Provide preprinted information on the most common disorders and treatments.
- Give the client phone numbers of past clients who are willing to discuss the realities of care and disease.
- Provide web site information on diseases.
- Tour the hospital and introduce the staff.
- Include the client in as much patient care as law and ethics will allow.
- Ask the client to summarize information.
- Follow up treatment with a phone call.

145.2 BUILDING THE TEAM (STEP 2)

The second step in providing excellent veterinary care is to build a team[1–3] of dedicated, caring, and knowledgeable individuals who are compatible in their vision, energy, compassion, and philosophy. Every member of the staff, from the practice manager, office personnel, technicians, nurses, and other staff, should understand that they each play a role in meeting the medical needs of the animal and the nonmedical needs of the client (Figure 145-1). This “team” extends beyond the clinic or hospital to incorporate pathologists, specialists, pharmacists, social workers, and others who should be included whenever possible to maximize quality care. The veterinary health care team should strive to include the client through education and the ability to provide ongoing day-to-day care and assessment. Without input from the client, care of the pet, regardless of the underlying disease, will not be optimal.

Figure 145-1 Each member of the veterinary health care team, especially veterinary nurses, should be incorporated in the care of patients and clients. When the entire team delivers care, it is more efficient, rewarding, and complete.

Forming a team is not easy. It requires careful selection of people who have similar goals and ideals and using their unique abilities and knowledge. Selecting, rewarding, and allowing people to support each other (as well as the pet and client) are important. Building a team also requires constant education and restructuring to meet the dynamic needs and growth of the team. Finally, it requires willingness to listen, to grow, and to allow the team to improve, evolve, and excel in serving the needs of the client and the patient.

145.2.1 Examples of Action Steps for Building the Team

To build the team, clinicians can do the following:

- Hire, pay, and promote only the best, most compassionate members.
- Frequently review and revise the mission statement and goals written by the team.
- Ensure the team interviews and participates in decisions involving the hiring of new members.

536

537

- Share and celebrate when clients or others recognize the work of the team.
- Meet at least weekly to listen to team members; value their input, feelings, and thoughts.
- Introduce nurses and receptionists to the client at the first visit. “Team” the case, and ensure each member of the team is aware of changes in the case.

145.3 DELIVER THE CARE (STEP 3)

Once the myths and misperceptions have been dissolved and a caring team is forged, the delivery of *compassionate care* can begin.[1–3] Compassionate care focuses not only on the pet in health and disease but also on the client (caregiver or “owner”) who has sought out veterinary care for the pet. Compassionate care is the outward manifestation of caring with both science and sincerity. This type of care should be operational in health and wellness, as well as in sickness and disease. Compassionate caring begins from the first moment of contact, through the process of making a diagnosis, to understanding the pathogenesis of the disease in the pet, to treatment of the condition, and finally to supporting the pet and client. After a diagnosis is made, then the real and perceived concerns should be addressed.

Delivering care can be done in several steps that can be divided into two main phases. The first phase involves providing caring support of the animal by anticipating or responding to the pet's medical needs and the client's nonmedical concerns. During this phase, the clinician should remember several things:

- Pain control is an extremely important medical priority. The use of analgesics, especially to prevent pain, will reassure the caregiver that quality of life is important. This can be in the form of oral medications (morphine, codeine, feldene, carprofen, or others), transdermal delivery systems for fentanyl, and intravenous delivery systems.
- Preventing or treating nausea, vomiting, and diarrhea is important for the pet and client. With the availability of new drugs and knowledge of the ways therapies can be administered with few adverse effects, nausea and vomiting as a result of chemotherapy can be minimized. Other chapters in this book provide details on specific medications for these problems.

- The veterinarian, client, and other members of the team often accurately perceive appetite and adequate nutritional intake as integral with quality and quantity of life. Nutrients and specific dietary profiles have been shown to be helpful for cardiac disease, diabetes, gastrointestinal (GI) disorders, renal disease, and even cancer. Basic nursing care is valuable (warming food, providing aromatic foods and comfortable environments). These animals may benefit from medicinal appetite stimulants and, when needed, assisted-feeding techniques such as esophagostomy, gastrostomy, or jejunostomy tube placement.

The second phase of delivering care involves providing direct therapy for the underlying disease. Each phase of the process of compassionate care is interdependent on the others. In addition, each client has his or her own goals for quality and length of life, as well as personal limits regarding adverse effects and cost of care.

145.3.1 Examples of Action Steps for Delivering the Care

To deliver care, clinicians can do the following:

- Avoid prejudging client desires and capabilities (review all options, regardless of cost or outcome).
- Discuss team philosophy for patient care with the client.
- Outline the steps to prevent toxicity or illness.
- Outline the procedure to follow if problems occur, including plans for weekends, nights, and holidays.
- Provide the client with information about the particular disease and its treatment (the goal should be to have clients know as much as possible).
- Anticipate and listen to client's needs, goals, and concerns.

145.4 SETTING THE GOALS FOR CURE, CONTROL, OR SUPPORT

As mentioned previously, all options should be given for each pet, regardless of the disease, from the very highest level of curative treatment, to palliative therapy, to supportive and hospice care, and finally to euthanasia. Each client should be allowed to make the choice and set goals for cure, control, or support[1–3] that are appropriate for them; clients should be made to feel that their decisions will be honored and supported by the entire team. The following are a few of the options that may be considered for each dog or cat:

- Definitive, curative intent: Cure is the goal of every client and veterinary health care team, it is often mistaken as the only goal. The success rate of curative intent is improved by determining what disease exists and by planning to achieve these curative goals while maintaining quality of life.
- Palliative care: Palliative care is treatment of a dog or cat to improve quality of life but not necessarily the length of life. For example, course fraction radiation to a site of bony metastasis is primarily designed to alleviate pain but will not cure the animal of its cancer. This is commonly done in many non-neoplastic, chronic diseases such as osteoarthritis and chronic renal failure.
- Supportive care: Little difference exists between palliative and supportive care. Both are defined as treatment to improve quality of life without necessarily lengthening life. Supportive care often implies minimizing clinical signs rather than direct treatment of a disease. Supportive care is often used in

combination with all forms of care, including palliative care. The clinician provides supportive care by administering such drugs as analgesics, antiemetics, appetite stimulants, as well as treatments for anemia and leukopenia.

- Hospice care: Hospice care is a type of supportive care; however it is usually defined as comfort or supportive care at the end of life. Hospice care, or care to maintain quality of life, especially comfort in the terminal phases of a disease, is a defined specialty in human medical care. This type of care is developing in veterinary medicine. Dignity and comfort until death, whether due to euthanasia or a natural death, may be important to many clients and veterinarians. As with palliative and supportive care, hospice care requires careful client communication. The client and the veterinary health care team need to define goals and realistic expectations. Boundaries and limits have to be set by both sides, with the intent of providing compassionate care for the patient.

- When philosophic differences exist between the veterinary health care team and the client, referral to another center may be necessary. If support groups or counselors with specific training in pet loss and bereavement exist, their expertise should be used when appropriate (usually before a moment of crisis). In addition, creating a plan for a natural death or euthanasia is important, preferably at a time when objectivity is possible.

- Euthanasia and bereavement: It is essential that the entire team handle this portion of life through adequate client preparation. An ongoing dialogue between the entire veterinary health care team and the caregivers should exist prior to (and at the time of) death and euthanasia.

537

538

145.4.1 Examples of Action Steps for Establishing Goals

To establish goals, clinicians can do the following:

- Review all the possibilities for cure, palliation, support, terminal care, and euthanasia (include cost, time requirements, potential toxicity, and probability of success of care).

- Educate the client that care is often a cascade from palliation and support to hospice care and finally to euthanasia.

- Set milestones of time to review goals using medical information in combination with emotional support.

145.5 COST OF CARING: COMPASSION FATIGUE

Providing compassionate care requires the ability to express empathy. When we fail to express empathy, then we separate compassion from caring. It is in the action of this empathetic response that can lead to “compassion fatigue.”[4] Simply put, compassion fatigue is the depletion of resources from within as we care for others. This development is not a reflection of the character, professionalism, or even professional skill, but rather the strength and willingness to be emotionally engaged with another being that is hurting. This condition is often “diagnosed” by well-meaning individuals as another entity known as *burn out;* however, compassion fatigue is a distinct entity with unique symptoms, outcome, and treatment.

Symptoms of compassion fatigue are often nonspecific but include psychological, emotional, behavioral, work-related, and interpersonal symptoms. Mild symptoms can include lowered frustration tolerance, loss of confidence, dread of working with certain clients, subtle manipulation of clients to avoid painful or traumatic

situations, and loss of enjoyment of one's career. The more severe symptoms can result in reduced functioning in and out one's job situation.

Prevention and therapy are actually quite straightforward. The first step is to acknowledge that as caring professionals we are at risk for this condition. Compassion fatigue has struck and will strike us all. By recognizing the condition openly within each clinic and team, and by providing support and encouragement for each other, the symptoms can be more mild and recovery quicker. When we fail to recognize the condition and to support each other, compassion fatigue builds up until individuals become emotionally overwhelmed. One must take proactive steps to develop a balance between personal and professional life, as well as to establish and maintain boundaries.

145.5.1 Examples of Action Steps to Reduce or Treat Compassion Fatigue

To reduce or treat compassion fatigue, the clinician can do the following:

- Educate the entire veterinary health care team about compassion fatigue.
- Establish weekly debriefing sessions for the entire staff to discuss needs, concerns, and cases that weigh upon them.
- Form teams of professionals that look out for each other in the workplace and that identify high-risk moments for compassion fatigue.
- Identify professionals within the community who understand compassion fatigue, and notify team members regarding how to obtain access to these people.
- Establish a library for team members, with books and resources on compassion fatigue.
- Identify a sanctuary or “comfort room” where team members can be alone, meditate, relax, and debrief.
- Ensure team members are fully informed about each case and are allowed to have adequate closure at the end of any patient's life.
- Whenever possible, work out sabbatical or continuing education opportunities for reward and growth. The break from caring can be very rewarding in the long run.
- Teach all staff members the correct limits and boundaries.
- Use humor whenever appropriate.

145.6 CONCLUSION

Compassionate care is nothing new, but rather one name of a brand of caring that defines veterinary medicine. This type of care springs from our hearts and minds and is innate. Compassionate care often begins most effectively by dispelling the myths associated with each condition, disease, and treatment. Replacing myths and misperceptions with facts and reality frees the team and client to ensure the care is unfettered. Clinicians can build a “team” by hiring those who have a similar vision and goals. This includes the receptionist, the nurses, the veterinarian, and all other members of the clinic or hospital. Compassionate care is delivered by the team but is not without risk if it is truly done from the heart. Indeed, compassion fatigue is the enemy of compassionate care.

146 CHAPTER • 146 Gene Therapy

Marilyn E. Dunn

***G**ene therapy* is defined as the introduction of new genetic and synthetic material into a living cell or organism for therapeutic purposes. In contrast to traditional therapeutics, in which a medication is administered to a patient to achieve a therapeutic response, gene therapy allows patients to "manufacture" their own treatment. Traditionally, gene therapy has been thought of as a method to treat monogenic (single gene) diseases, such as hemophilia; however, its scope has expanded to include the treatment of polygenic disorders of infectious, vascular, and neoplastic origin. New deoxyribonucleic acid (DNA) technology has been used to study the role of different genes and their products in disease. This technology has facilitated the diagnosis and treatment of these diseases by producing genetically engineered therapeutic proteins. The production of such proteins has been the basis of a number of clinical trials in both human and veterinary medicine. Although the majority of clinical trials performed to date have focused on human diseases, a growing number of trials are now being performed in veterinary medicine. Domestic animals increasingly are being recognized as ideal models for a number of human diseases.

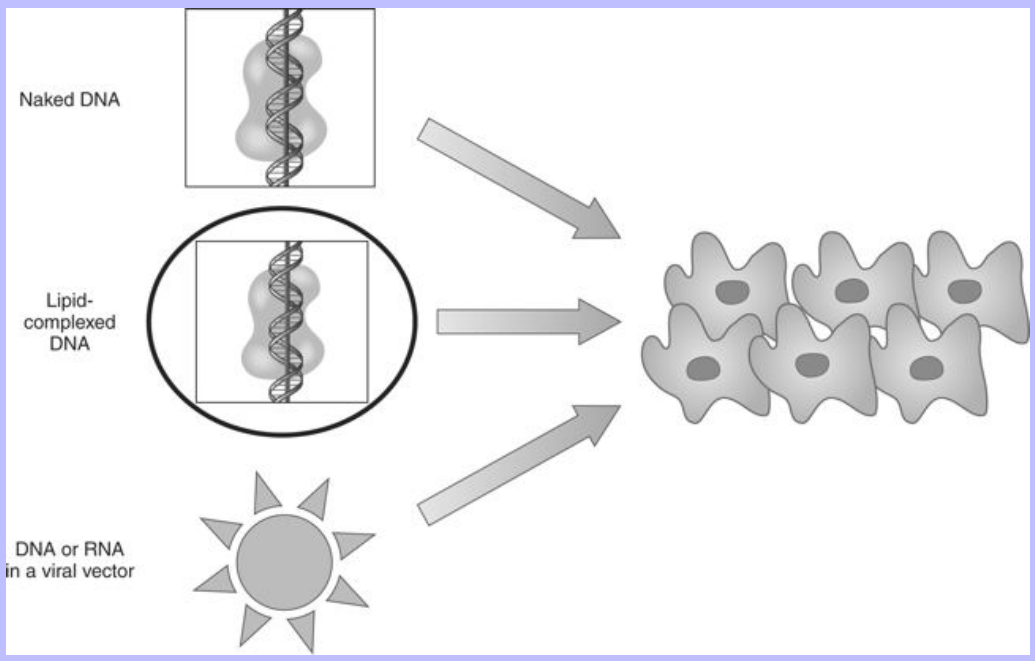
146.1 HISTORICAL BACKROUND

The term *genetic engineering* was first used in 1932 at the Sixth International Congress of Genetics and was taken to mean the application of genetic principles to plant and animal breeding. The term *gene therapy* was coined to distinguish this modality from genetic engineering. During the 1960s, the basics of molecular genetics and gene transfer in bacteria were established. In the late 1970s, recombinant DNA technology, the discovery of viral genomes, and the basics of gene transfer were established. In the early 1980s, the discovery of retroviruses led to more efficient gene transfer.[1]

In 1990 the first two approved *ex vivo* gene therapy trials in humans were performed in the United States. The first trial involved the use of gene therapy to correct for the enzymatic deficiency responsible for severe combined immunodeficiency syndrome (SCID), and the second trial involved the use of tumor necrosis factor (TNF) -transduced lymphocytes from tumors as immunotherapy for melanoma.[2] Both of these trials were unsuccessful, but they opened the door to a decade of intense research and clinical trials in the area of gene therapy.

In 1999, gene therapy suffered a major setback with the death of a young patient enrolled in a trial for a hepatic enzyme deficiency. This first death of a human patient enrolled in a gene therapy trial raised a number of ethical issues, which are still being actively debated. In 2000 the first two successful gene therapy clinical trials were reported. The first involved the successful treatment of two children suffering from SCID, also known as bubble-boy syndrome, using a retroviral vector for gene delivery.[3] The other reported the successful treatment of three hemophilia B patients using an adeno-associated viral vector for gene delivery.[4]

Figure 146-1 Methods of introducing genes into cells.



Over the past decade, research in human gene therapy has increased from two clinical trials in 1990 to 636 approved trials in 2002 involving over 4000 patients. The majority of these trials (64%) have focused on cancer research, 12% have focused on monogenic diseases, 8% on vascular diseases, and 6% on infectious diseases (primarily acquired immunodeficiency syndrome). Only 1% of the trials have thus far reached phase III.[5]

In veterinary medicine, three successful gene therapy trials have been reported: the correction of hemophilia B using an adeno-associated virus for gene delivery in five dogs; restoration of vision in three dogs afflicted with briard hereditary retinal dystrophy using an adeno-associated virus for gene delivery; and disease regression and prolonged survival in 12 dogs with malignant melanoma using cationic liposomes for gene delivery.[6]

146.2 SUCCESS FACTORS FOR GENE THERAPY

For gene therapy to be effective, the therapeutic gene must be transferred to the target cell and expressed at an appropriate level for a sufficient length of time to achieve the desired effect. The transfer and expression of the introduced gene must be safe for the cell and the animal being treated.

146.3 METHODS OF GENE TRANSFER

A gene may be transferred either by introducing it directly into a patient's cells *in vivo* (injection into a tumor) or by removing cells from the patient (e.g., bone marrow stromal cells), introducing the gene, and returning the cells to the patient (Figure 146-1). For gene transfer to occur, a vector or vehicle is required.[7]

146.3.1 Viral Systems

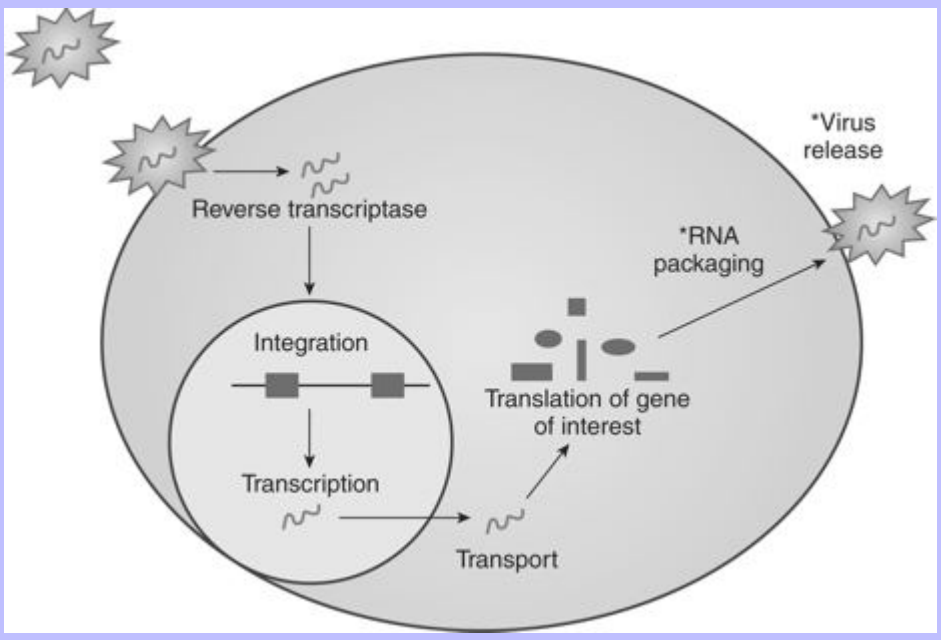
To date, the majority of gene therapy clinical trials have used viral vectors for gene transfer. Viruses have acquired biologic mechanisms over millions of years that make them ideal vectors. Viruses effectively recognize and enter cells, travel through the cytosol to the nucleus, translocate into the nucleus, and express their genes in the host cell.[8] Despite these many advantages, viruses also have a drawback: the ability to replicate within the host cell, resulting in the liberation of infectious viral particles. Because this is undesirable, viral vectors must be rendered *replication deficient* before they can be used for gene transfer. This is accomplished using molecular techniques that replace the viral gene's coding for replication with the therapeutic gene or genes of interest.[7]

146.3.1.1 Retroviral Vectors

Retroviruses are ribonucleic acid (RNA) viruses containing two copies of a single-strand RNA genome capable of integrating DNA within a host cell. Using a specific receptor, the retrovirus attaches itself to and enters a host cell. Viral RNA is then transcribed to DNA by viral reverse transcriptases and transported to the nucleus, where it integrates into the host genome. The *provirus,* or integrated viral DNA, is transcribed and translated to produce viral proteins. Some of the proteins are packaged, via a packaging signal, into viral capsids that bud from the host cell, releasing mature viruses (Figure 146-2). Retroviral vectors have been modified by substituting the gene of interest in place of certain viral protein coding regions (e.g., *gag, pol, env* regions). This substitution renders the vector replication deficient.[9]

Retroviral vectors are the most common vectors used in human gene therapy clinical trials. Their advantages include the ability to stably integrate themselves into a host, the lack of expression of viral proteins, and the ability to carry large amounts of DNA (8 kb). Their disadvantages include low titers, resulting in low levels of gene transfer; an inability to infect nondividing cells; and the risk of insertional mutagenesis.[8,10] The use of new envelopes or pseudotypes has conferred greater physical stability on retroviral vectors, allowing ultracentrifugation and the production of higher titers. Although the inability to infect nondividing cells can be perceived as a disadvantage, in cancer gene therapy, it can be quite useful. Retroviral vectors can be used to target dividing cancer cells specifically without affecting nondividing surrounding tissue. An example is the use of a retroviral vector in the treatment of brain cancer. The vector can integrate itself into the cancer cells without affecting surrounding nondividing nerve tissue.[11]

Figure 146-2 Retrovirus replication cycle. The asterisk (*) indicates elements that are absent in a retroviral vector.



146.3.1.2 Adenoviral Vectors

Adenoviruses are double-strand DNA viruses with a tropism for epithelial cells. Unlike retroviruses, which insert themselves into the host's genome, adenoviruses remain episomal or extrachromosomal. Adenoviral vectors are made replication deficient by the removal of genes in the E region. Genes of interest can then be inserted into the adenoviral vector.[9]

The advantages of adenoviral vectors are that they can infect both dividing and nondividing cells; they can be produced in high titers; and they can carry large amounts of DNA (10 kb). However, given their episomal expression, adenoviral vectors do not lead to stable integration of the host genome, which results in transient gene expression. This short-lived effect often requires multiple treatments with an adenoviral vector to maintain therapeutic gene expression. Adenoviral vectors are highly immunogenic and lead to a marked immune response, which may interfere with repeated applications. Given their tropism for epithelial cells, adenoviral vectors have been used extensively in gene therapy research for cystic fibrosis.[12] Although their short-lived effect and ability to provoke an intense immune response may be perceived as disadvantages, these characteristics may be useful in cancer gene therapy in which short-term protein expression accompanied by a marked inflammatory response is desirable.[9,10]

146.3.1.3 Adeno-Associated Viral Vectors

Adeno-associated viruses (AAVs) are small, single-strand DNA viruses that replicate only in the presence of a helper virus, such as an adenovirus or a herpes simplex virus. In the absence of a helper virus, an AAV cannot replicate but can integrate itself into the host genome. Therefore, compared with adenoviral vectors, an AAV results in more stable, prolonged gene expression. Although the process is technically difficult, AAVs can be produced in high titers; however, a major limitation to their use is their small size, which restricts their DNA carrying capacity to 4 kb.[10,13] Unlike adenoviruses, AAVs do not contain viral coding sequences and thus do not lead to immune or inflammatory responses. To produce an AAV, a helper virus is required. Contamination of the AAV preparation by a pathogenic helper virus (adenovirus or herpes simplex virus) is a concern.[13]

540

541

146.3.2 Nonviral Systems

Nonviral methods of gene transfer are generally less efficient, resulting in low gene transfer rates. These vectors do not integrate into the host genome, and consequently the majority of DNA molecules entering the cell are rapidly degraded, resulting in only transient gene expression. These methods are best used when long-term gene expression is unnecessary, such as in cancer gene therapy in which transient immune modulation is beneficial or in vaccination with naked DNA.[7]

Nonviral vectors are desirable, because they can be produced under controlled conditions, eliminating the risk of viral contamination.

146.3.2.1 Naked DNA

Nucleic acid injected directly into a cell is taken up and expressed by the cell and thus can serve as a method of gene delivery. Short-term gene expression makes this method potentially useful for the development of nucleic acid–based vaccines in both human and veterinary medicine.[9]

146.3.2.2 DNA in Cationic Liposomes

Positively charged cationic liposomes attach to DNA, forming a lipid-DNA complex. The complex binds to the cell membrane and increases the efficiency of gene transfer. These complexes have been used to deliver genes to the lungs by aerosol[14] and by intratumoral injection.[15] Currently, receptors are being incorporated into the lipid-DNA complex to target specific tissues.

146.3.2.3 Particle-Mediated Gene Transfer

Nucleic acid is adsorbed onto gold beads, which are then shot under pressure by a “gene gun.” The DNA-coated gold beads are propelled into cells, resulting in transient gene expression. This method of gene transfer has been used *in vivo* to transfect epithelial cells, giving it a potential role in veterinary DNA vaccination.[7]

146.3.2.4 Cell-Based Delivery of Therapeutic Genes

Therapeutic genes can be delivered by *ex vivo* manipulation of cells, which are then reintroduced into a patient. Hematopoietic stem cells, mesenchymal stem cells, neuronal stem cells, and embryonic stem cells are preferred for this type of delivery because of their pluripotential capacity or ability to give rise to various cell lineages. Currently, much stem cell research is under way to select vectors that will provide efficient stem cell gene transduction, control of gene expression during lineage progression, and control of stem cell growth and differentiation *in vivo*.[8]

Stem cell research has caused considerable controversy and raised a number of ethical issues that currently are being debated.

146.4 CLINICAL APPLICATIONS OF GENE THERAPY IN VETERINARY MEDICINE

Gene therapy has been an area of intense research in human and veterinary medicine over the past 15 years. Gene therapy can be used to treat diseases as varied as monogenic diseases, cardiovascular disease, and cancer. Advancements in gene therapy have been made in a number of areas, although no U.S. Food and Drug Administration (FDA)–approved gene therapy products are commercially available.

146.4.1 Monogenic Diseases

As mentioned previously, gene therapy initially was thought of as a way to correct single-gene defects, such as are present in monogenic diseases. The first human gene therapy clinical trial was performed on a patient suffering from SCID, which is the result of an adenosine deaminase deficiency that causes the loss of T lymphocytes. In human medicine, hemophilia, cystic fibrosis, thalassemia, and hereditary retinal dystrophy (Leber amaurosis) have been investigated as targets for gene therapy. In veterinary medicine, gene therapy has been successful in the correction of briard retinopathy and hemophilia B in the dog.

Briard retinopathy and its human counterpart, Leber congenital amaurosis, both result in retinal dystrophy secondary to a single-gene mutation in the retinal pigment epithelium. This mutation causes the accumulation of toxic metabolites in the retina, leading to progressive degeneration and complete blindness. In the study, an AAV carrying the gene of interest was injected subretinally in three dogs suffering from briard retinopathy. All three dogs in this study, which were blind initially, had complete restauration of vision. Unfortunately, it was not stated in the study whether the improvement was sustained.[16]

Two canine studies have successfully shown long-term phenotypic correction of hemophilia B. The first study demonstrated partial phenotypic correction of hemophilia B in five dogs using an AAV administered by percutaneous intramuscular injection into the tibialis anterior and vastus lateralis muscles. All dogs had a marked rise in factor IX, which prevented spontaneous bleeding episodes; however, coagulation profiles were prolonged, and the dogs still bled with moderate trauma. Thirteen months after AAV administration, factor IX plasma levels were maintained.[17]

The second study demonstrated almost complete phenotypic correction of hemophilia B in three dogs after a liver-directed AAV was administered through a mesenteric vein. All dogs had resolution of bleeding episodes and correction of coagulation profiles. Seventeen months after AAV administration, factor IX plasma levels were maintained.[18]

The question is, despite these apparent successes, why are only 12% of the clinical trials being performed in human medicine focusing on monogenic diseases? One reason is the fact that monogenic disorders are less common than other diseases, such as cardiovascular disease and cancer, therefore the benefits would be felt by a smaller clinical population. Also, current vectors are more suited to cancer therapy, given the difficulty of achieving long-term gene expression.

Monogenic disease is managed differently in veterinary medicine than in human medicine in that breeding programs designed to eliminate the disease can often be accomplished. However, animals suffering from these diseases can serve as models for their human counterparts.

146.4.2 Cancer

The most popular disease target in gene therapy is cancer. Despite great advances in human and veterinary oncology, cancer remains a disease with high morbidity and mortality. This reality has fueled the search for alternative treatments, such as gene therapy.

Cancer gene therapy has six major approaches, which involve introduction of (1) a suicide gene, (2) a cytokine gene, (3) a tumor suppressor gene, (4) an antisense oncogene, or (5) a multiple drug resistance gene, and also (6) inhibition of angiogenesis (Figure 146-3).

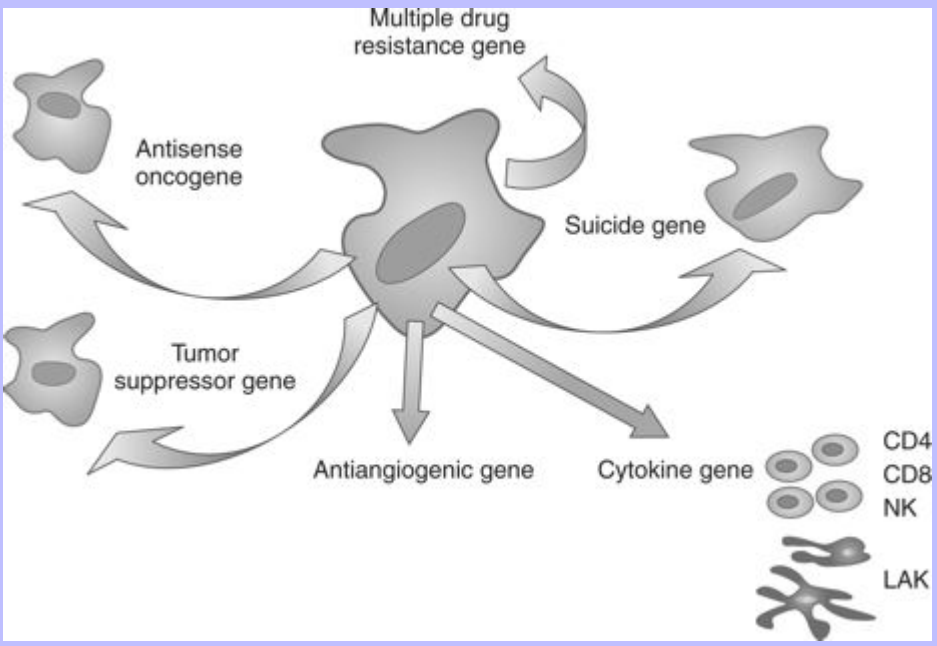
146.4.2.1 Suicide Gene

A suicide gene is one that codes for a specific enzyme that is capable of metabolizing a substance into a toxic metabolite. In one study, a retrovirus containing a thymidine kinase gene was injected intratumorally into human patients with brain tumors. Gancyclovir, which is metabolized to a toxic metabolite by thymidine kinase, was then administered systemically. Small tumors showed partial regression, but larger tumors did not respond. Because retroviruses can infect only dividing cells, surrounding nervous tissue was unaffected.[19] It is believed that a *bystander effect* is partly responsible for some of the successes achieved with suicide gene therapy. The bystander effect is thought to be mediated by the transfer of toxic metabolites from one transduced cell to surrounding cells. The immune reaction secondary to cell death also plays a role in the bystander effect. Currently, suicide gene therapy is being investigated for the treatment of malignant melanoma in the dog.[7] One of the hurdles that must be overcome in suicide gene therapy is low tumor transduction, which often results in poor or partial responses to therapy.

541

542

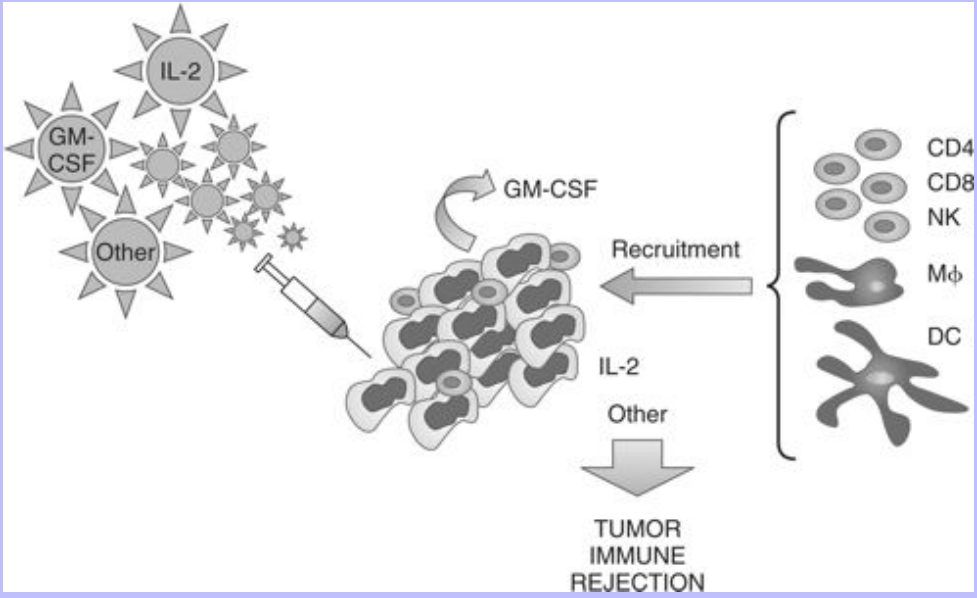
Figure 146-3 Potential targets of cancer gene therapy. *NK,* Natural killer cells; *LAK,* lymphokineactivated killer cells.



146.4.2.2 Cytokine Gene

Cytokine genes can be inserted directly into tumor cells, allowing recognition of the tumor cell and distant metastases by the immune system (Figure 146-4). This process has been referred to as *tumor vaccine*. The term *autologous tumor vaccine* refers to *ex vivo* transduction of autologous tumor cells, which are then reintroduced into the patient.[20] In one study, histoincompatible cells expressing interleukin-2 (IL-2) were introduced into animals with spontaneous canine malignant melanoma and feline fibrosarcoma. The outcome of this study was favorable in that treated animals showed improved survival compared with controls.[21] Another study evaluated the effect of intratumoral injection of lipid-complexed DNA encoding for a bacterial superantigen and either IL-2 or granulocyte-macrophage colony stimulating factor (GM-CSF) in 26 dogs with malignant melanoma. This therapy was capable of inducing both local and systemic tumor regression, with an overall response rate of 46%.[22] Another study evaluated the usefulness of an autologous tumor vaccine transfected with GM-CSF in 16 tumor-bearing dogs. Evidence of an antitumor response was seen in three dogs.[23] Despite these encouraging results, a number of other clinical trials have showed marked variability in tumor response to cytokine therapy.

Figure 146-4 Retroviral vectors coding for interleukin-2 (IL-2), granulocyte-macrophage colony stimulating hormone (GM-CSF) or other cytokines can be introduced directly into tumor cells. These tumor cells produce cytokines, resulting in recruitment of inflammatory cells that leads to immune tumor rejection. *M,* Macrophage; *DC,* dendritic cell.



146.4.2.3 Tumor Suppressor Gene

Cancer can result from mutations or deletions in the tumor suppressor gene, resulting in uncontrolled cell growth. The introduction of a tumor suppressor gene (e.g., p53 gene) into a tumor cell can prevent the cell from entering into the cell cycle, thereby leading to *apoptosis* (programmed cell death). In a human clinical trial, 28 patients with lung cancer were treated by intratumoral injection of an adenovirus containing the p53 gene. Eight percent of the patients showed a partial response, but the treatment had no effect on distant metastases.[24] The lack of vectors capable of efficient systemic gene delivery thus far has limited the usefulness of this approach.

542
543

146.4.2.4 Antisense Oncogene

Oncogenes are genes that, when mutated or overexpressed, result in uncontrolled cell growth. Antisense oligodeoxynucleotides are short sequences of RNA that are complementary to the messenger RNA (mRNA) of an oncogene. The antisense oncogene blocks tumor RNA transcription, blocking tumor protein synthesis and thereby leading to tumor cell apoptosis. Human clinical trials, using antisense oncogenes, have demonstrated partial responses in a small number of patients. A major limitation to this approach is the inability to deliver antisense oncogenes efficiently to tumor cells.[9]

146.4.2.5 Multiple Drug Resistance Gene

Expression of the multiple drug resistance (MDR) gene decreases toxicity from certain chemotherapeutic drugs such as doxorubicin, vincristine, and actinomycine D by encoding for a transmembrane pump. Expression of the MDR gene by tumor cells is associated with resistance to chemotherapy. Human clinical trials have used this approach primarily in the treatment of leukemic patients. Healthy bone marrow hematopoietic cells are withdrawn from the patient, transduced with the MDR gene, and reinfused. The goal of this approach is to decrease hematopoietic toxicity from chemotherapy by rendering the healthy hematopoietic cells chemoresistant. Some of the difficulties encountered with this approach are poor hematopoietic cell transduction and the occurrence of nonhematopoietic toxicities with the use of high-dose chemotherapy protocols.[8]

146.4.2.6 Inhibition of Angiogenesis

In 1970, Folkman discovered that tumors produce substances that stimulate the growth of their vasculature.[25] These substances have since been identified as proangiogenic cytokines. Angiogenesis can be inhibited by blocking the production of proangiogenic cytokines. For example, the VHL gene has been shown to downregulate vascular endothelial growth factor in human renal cancer cells.[9] Angiostatin, endostatin, and interleukin-12 are known to be endogenous inhibitors of angiogenesis. Transduction of tumor cells resulting in expression of these inhibitors, has been shown to decrease tumor angiogenesis in murine models.[26]

In the future, combined approaches to cancer gene therapy may prove to be most beneficial. For example, introduction of both a suicide and a cytokine gene into tumor cells may result in a local tumor effect and a systemic immune response directed at distant metastases.

146.4.3 Other Potential Veterinary Applications

Inflammatory, infectious, and cardiovascular diseases are areas in which much gene therapy research currently is under way. Inflammatory conditions such as osteoarthritis and rheumatoid arthritis, which are influenced by the aberrant expression of certain inflammatory cytokines, have been targets of such research.[27] Gene therapy approaches have also been applied to certain infectious diseases, in particular that caused by the human immunodeficiency virus (HIV). One such approach is the transfer of antiviral genes to hematopoietic stem cells to ensure a renewable source of HIV-protected cells to the patient.[28] If successful, these approaches could be used in the treatment of cats infected with feline immunodeficiency virus (FIV).

The usefulness of gene therapy in the treatment of cardiovascular disease in humans has recently been investigated. Attempts are being made to develop vectors that can efficiently deliver genes into the myocardium to treat myocardial infarction and into the vasculature to treat atherosclerosis. These therapies could be used in veterinary medicine to treat patients with myocardial disease.[8]

146.5 CONCLUSION

Gene therapy is a relatively new area of research that has yielded a multitude of research protocols but thus far has resulted in few clinically applicable treatments. Gene therapy success has been limited by difficulties in delivering genes safely and efficiently to target cells. In the future, advances in vector design may help overcome some of the

hurdles currently encountered. Other issues, such as the risk of insertional mutagenesis and the production of replication-competent viruses, as well as ethical concerns, also need to be addressed.

147 CHAPTER • 147 Constant Rate Infusions

Nishi Dhupa

A constant rate infusion (CRI) is a precisely calculated amount of drug added to a specific volume and type of diluent fluid, delivered as a continual IV infusion for the duration of the treatment period. The intent of drug therapy is to produce the desired pharmacologic response while avoiding adverse drug reactions. Drugs with very short half-lives, such as dobutamine or epinephrine (less than 2 minutes) and nitroprusside (0.4 minutes), must be administered by CRI to maintain steady-state serum concentrations and achieve desired pharmacologic effects. Other drugs such as furosemide may be delivered by CRI to increase efficacy and to reduce total daily dose.

147.1 PHARMACOKINETICS

The drug half-life is defined as the time it takes for the blood concentration of the drug to diminish by 50% and is a function of both clearance and volume of distribution. The half-life predicts how long it takes for a drug-dosing regimen to achieve steady-state serum concentrations. With initiation of therapy, if a loading dose is not administered to provide “instantly” a desired serum drug concentration, four to five half-lives will elapse before the patient reaches steady-state drug concentrations. For drugs with very short half-lives (less than 2 minutes), loading doses may not be required. Many cardiac and vasoactive drugs fall into this category. When delivered by CRI, immediate hemodynamic improvement can be achieved and the dose can be titrated to achieve desired effects.

147.2 PHARMACEUTICAL DRUG INTERACTIONS

The safe use of parenteral drugs depends on the drug's pharmaceutical integrity, including stability and compatibility. Pharmaceutical drug interactions occur before a drug is administered to the patient *(in vitro)*. These interactions occur primarily because of a drug's physical incompatibility with another drug or fluid solution (acid-base interactions or affinity to charged particles in another solution) or the drug's container (including intravenous tubing). Drug solutions are formulated to ensure their chemical stability; mixing drugs with different preservatives, vehicles, and buffers compromises this stability. These concerns apply most to the veterinary critical care environment, where multiple drug administration is common. Drug incompatibilities can change the chemical or physical nature of the drug and can influence efficacy and toxicity. Although many unstable solutions do not show obvious changes, any change in solution color (or the development of cloudy precipitates) should halt administration and elicit inquiry. Some color changes, such as a pink discoloration of dobutamine solutions, may not affect potency if used within 24 hours; conversely a violet or pink dopamine solution indicates inactivation.

The stability of a drug in fluids is related to an optimal pH and therefore diluent solutions must be chosen carefully. Saline solutions have a pH of 5 to 6, and 5% dextrose solutions have a pH of 5. These may be used as diluents for drugs that are weak bases (formulated as salts of hydrochloric acid) and must be kept in acidic state to maintain their stability in aqueous solution. Examples of these drugs include dopamine, dobutamine, epinephrine, and isoproterenol; they are incompatible in alkaline solutions. Questions regarding the stability of drugs and interactions between drugs in solution can be answered by reading the package insert of each drug and various excellent publications.[1]

The adsorption of drugs to plastic or glass surfaces may result in variable dose delivery. Highly lipid-soluble drugs such as diazepam will lose a significant amount of potency when administered through plastic infusion tubing at slow flow rates. Regular insulin (used as a CRI for treatment of diabetic ketoacidosis) binds to glassware and

many plastics. This binding process can be saturated, and the flushing of intravenous lines with a sufficient volume (50 mL) of the drug in solution prior to administration will result in more accurate dosing. Drugs such as nitroprusside, which manufacturers package in brown containers, may be sensitive to light. Care should be taken to provide protection from ultraviolet (UV) light during infusion.

147.2.1 Specific Drugs

A list of drugs administered as CRI in small animal veterinary medicine is presented in Table 147-1. The most common CRI drugs are positive inotropes (dobutamine, dopamine), pressor agents (epinephrine, norepinephrine), vasodilators (nitroprusside), and antiarrhythmics (lidocaine, procainamide).

147.2.2 Dose Calculation and Constant Rate Infusion Preparation

CRI doses must be calculated carefully. In general, doses for most CRI drugs are expressed as *micrograms per kilogram of body weight per minute*, but the drugs themselves are available in concentrations of *milligrams per milliliter*. Therefore dose calculations must convert from micrograms (μg) to milligrams (mg) to ascertain the volume of drug required. The objective is to determine how much drug to add to a specific volume of diluent fluid to achieve the required dose: *μg × kg × min = μg of drug to be added to a known volume of diluent fluid.* In this formula, the microgram (μg) dose and the body weight (kg) of the patient is known; the number of minutes that each bag of intravenous fluid will last is calculated by dividing the volume in the fluid bag by the fluid administration rate per hour; then multiplying this by 60 to determine the number of minutes. The formula can then be solved to provide the total number of micrograms required for addition to the fluid bag; this can be divided by 1000 to convert the dose to milligrams. With a known concentration of drug (mg/mL), the required volume can be added to the diluent intravenous fluid bag. For precise dosing, the equivalent volume of diluent fluid should be discarded prior to addition of drug to the diluent solution.

Note: For infusions lasting exactly 1000 minutes (e.g., 250 mL fluid bag infused at 15 mL/hour or 500 mL infused at 30 mL/hour), a simpler formula may be used: *μg × kg = mg of drug required.* 544 545

Example 1: The clinician must calculate a dobutamine CRI in 0.9% saline at 10 μg/kg/minute for a 20 kg dog in septic shock. Using the previous formula (μg × kg = mg of drug required) the clinician would add 200 mg of dobutamine to 250 mL of saline, to infuse at 15 mL/hour. The concentration of dobutamine is 12.5 mg/mL; therefore 16 mL of dobutamine will be added to 234 mL of saline (16 mL removed prior to addition of the drug).

Table • 147-1 Drugs Administered Via Constant Rate Infusions*

DRUG NAME AND FORMULATION	ACTIONS AND INDICATIONS	CONSTANT RATE INFUSION (CRI) DOSE	RECOMMENDED DILUENT (D) AND INCOMPATIBILITIES (I)	COMMENTS
Atracurium besylate 10 mg/mL	Competitive neuromuscular blockade; induction of respiratory muscle paralysis during mechanical ventilation	LD: 0.2–0.5 mg/kg IV (dog and cat) CRI: 3–9 µg/kg/min (dog) 0.37 µg/kg/min (cat)	D: 5% Dextrose, 0.9% NaCl I: should not be mixed with other Drugs	Infusion started 5 min. after loading dose; respiratory and cardiovascular monitoring should be provided
Butorphanol 10 mg/mL	Synthetic opiate; analgesia +/−sedation	LD: 0.2 mg/kg CRI: 0.1 mg/kg/hr	D: Any IV fluid I: Diazepam, pentobarbital	Partial agonist
Calcium gluconate 100 mg/mL	Treatment of hypocalcemia, hyperkalemic dysrhythmias, hypermagnesemia	CRI: 10 mg/kg/hr	D: Any IV fluid I: Dobutamine, sodium bicar-bonate, potassium phosphate	ECG should be monitored; CRI should be discontinued if bradycardia develops
Cimetidine 300 mg/2 mL	H_2 receptor antagonist; used in treatment of gastric ulceration, metabolic alkalosis	LD: 2.5 mg/kg CRI: 0.5 mg/kg/hr	D: Any IV fluid I: Pentobarbital, atropine	Too rapid an infusion or use of a central vein may cause hypotension and arrhythmias
Cisplatin 1 mg/mL	Cell cycle nonspecific antineoplastic agent; used for various neoplasms	CRI: 60–70 mg/m^2 over 2–6 hours	D: 0.9% NaCl I: Metoclopramide	Should not be used in cats; saline diuresis should be provided to avoid nephrotoxicity
Diazepam 5 mg/mL	Enhances effects of GABA in the brain; anticonvulsant, sedative, and skeletal muscle relaxant effects (tetanus)	LD: 5–10 mg CRI: 0.1–0.5 mg/kg/hr; increase to effect	D: 5% Dextrose, 0.9% NaCl I: Many drugs†; cloudiness in admixture indicates precipitation and reduced potency	Adsorbs to plastic IV tubing resulting in unreliable dosing; does not adsorb to plastic syringes; should be protected from light; new infusion should be started every 4 hours
Diltiazem 5 mg/mL	Calcium channel blocker, negative inotropic and chronotropic effect; used in hypertrophic cardiomyopathy and supraventricular tachycardias	LD: 0.2–0.4 mg/kg CRI: 0.2–0.5 mg/kg/hr or 5–20 µg/kg/min consulted) to effect	D: Any IV fluid I: None listed (drug insert should be	Loading dose is not always used
Dobutamine 12.5 mg/mL (250 mg/20 mL vial)	Synthetic catecholamines; positive inotrope via beta effect; useful in cardiogenic or septic shock to treat decreased cardiac contractility	2–20 µg/kg/min (dog) 1–15 µg/kg/min (cat)	D: 5% Dextrose or 0.9% NaCl I: Alkaline solutions, sodium bicarbonate; mixing with other drugs should be avoided†	Pink discoloration occurs with slight oxidation, but no loss of potency if used within 24 hours; may cause focal facial seizures in cats

Dopamine 40 mg/mL (200 mg/5 mL)	Low dose: Dopaminergic at low dose; improves renal blood flow; may play a role in treatment of oliguric renal failure	2–5 µg/kg/min	5% Dextrose or 0.9% NaCl I: Sodium bicarbonate or alkalinizing solutions	Do not use if solution has a pink or violet color; stable in fluids for 24–48 hours; extravasation may cause necrosis; should be treated locally with 5–10 mg phentolamine in 10–15 mL saline
	Moderate dose: Beta agonist and positive inotrope at moderate dose	5–10 µg/kg/min		
	High dose: Pressor agent at high dose; increases blood pressure	7–20 µg/kg/min		
Epinephrine 1:1000 (1 mg/mL)	Alpha and beta agonist, positive inotrope and chronotrope; used in cardiac arrest, hypotension, severe asthma, and anaphylaxis	0.1–1.5 µg/kg/min to effect	D: 5% Dextrose or 0.9% NaCl I: Alkaline solutions; calcium-containing solutions	Solution should be protected from light
Esmolol 10 mg/mL	Short-acting beta-1 (cardioselective) blocker; used in tachycardia or hypertension	LD: 500 µg/kg (over 1 min) CRI: 25–200 µg/kg/min	D: 5% Dextrose, 0.9% NaCl I: Sodium bicarbonate	Concurrent use of calcium channel blockers should be avoided
Ethanol 100% (1000 mg/mL)	Treatment of ethylene glycol toxicity	LD: 0.6 g/kg CRI: 100 mg/kg/hr	D: 0.9% NaCl to a 7% solution I: None listed	7% solution is prepared by adding 7 mL 100% ethanol to 93 mL NaCl
Fentanyl citrate 0.05 mg/mL (50 µg/mL)	Narcotic analgesic; synthetic opioid; used for analgesia and sedation; may be used to facilitate mechanical ventilation	LD: 10–20 µg/kg IV (dog) CRI: 0.3–0.7 µg/kg/min (dog) LD: 2 µg/kg (cat) CRI: 0.1–0.3 µg/kg/min (cat)	D: 5% Dextrose I: Mixing with other drugs should be avoided	Alternative dose: 1–5 µg/kg/hr
Furosemide 50 mg/mL	Loop diuretic; promotes diuresis in oliguric renal failure, treats pulmonary edema in CHF, promotes calciuria in hypercalcemia	3–8 µg/kg/min or 0.1–1 mg/kg/hr to effect	D: Any IV fluid I: Acidic solutions; precipitates when combined with many drugs[†]	Should be protected from light
Heparin 1000 U/mL	Activates antithrombin III, prevents thrombin and fibrin formation; used in DIC and throm-boembolic disease	LD: 100–300 U/kg CRI: 10–50 U/kg/hr (dog) 5–10 U/kg/hr (cat)	D: Any IV fluid I: Any drugs that are unstable in an acidic environment[†]	Adjust dose based on activated partial thromboplastin time; clinician should aim for increase of 1.5–2.5 times original rate

Hetastarch 6 g/100 mL	Synthetic colloid; used for its oncotic properties and as a volume expander	1–2 mL/kg/hr	Available as a 6% solution in 0.9% NaCl	Should not be used if brown in color or precipitate present
Hydrocortisone sodium phosphate 100, 250, or 500 mg vials	Treatment of addisonian crisis and of adrenal insufficiency induced after adrenalectomy	0.625 mg/kg/hr	D: Any IV fluid; should be diluted to 0.1–1.0 mg/mL I: Mixing with other drugs should be avoided†	Proper dilution volume should be used to avoid precipitation; should not be administered if discolored
Insulin (regular) 100 U/mL	Lowers blood glucose, used in diabetic ketoaci-dotic patients and for adjunctive treatment of hyperkalemia	1.1–2.2 U/kg/day (use lower doses for cats)	D: 0.9% NaCl I: Sodium bicarbonate; mixing with other drugs should be avoided†	Binds to IV tubing; tubing should be flushed with insulin solution prior to IV infusion
Isoproterenol 0.2 mg/mL (1 mg/5 mL)	Beta-adrenergic agonist, causes positive inotropy and chronotropy; also vasodilator and bronchodilator; used in advanced heart block	0.02–0.1 µg/kg/min	D: 5% Dextrose or 0.9% NaCl; dilute to 1 mg in 500 mL (1:500,000 solution) I: Sodium bicarbonate	Causes peripheral vasodilation
Ketamine 100 mg/mL	Neuroleptanalgesia; may be used as an adjunct to opioid therapy to ease severe pain	1–3 µg/kg/min; clinician should prepare a 1–2 mg/mL solution (500 mg added to 500 mL)	D: 5% Dextrose or 0.9% NaCl I: Diazepam, barbiturates	Should be used with opioid or tranquilizers
Lidocaine 20 mg/mL (2%)	Class IB ventricular antiarrhythmic	LD: 2–4 mg/kg (dog) CRI: 50–100 µg/kg/min (dog) LD: 0.25–0.75 mg/kg (cat) CRI: 10–20 µg/kg/min (cat)	D: 5% Dextrose; 0.9% saline less preferred I: Alkaline solutions; mixing with other drugs should be avoided†	Adsorption to polyvinyl chloride bags; stable in IV fluids for 24 hours; cats are very sensitive to the drug (may seizure)
Magnesium sulfate (parenteral) 4.06 mEq/mL 50% (500 mg/mL)	Used as a source of magnesium in hypomagnesemia and refractory hypokalemia	Up to 1 mEq/kg/day	D: 5% Dextrose diluted to <20% I: Many drugs,† including those containing calcium, vitamin B complex, sodium bicarbonate	Use with caution with impaired renal function; overdose causes bradycardia, muscle weakness; treat with calcium
Mannitol 25% (250 mg/mL)	Osmotic diuretic; free radical scavenger; has a role in treatment of oliguric renal failure, glaucoma, cerebral edema	0.5–1 g/kg/hr for 2–6 hr	D: 5% Dextrose to 8% -10% solution I: Blood, strongly acidic or alkaline solutions; mixing with other drugs should be avoided	Clinician should warm to remove crystallization of high (25%) concentrations; easier in glass containers than plastic

Methylprednisolone sodium succinate 40 mg/mL	Treatment of head/spinal cord trauma	LD: 30 mg/kg followed by 15 mg/kg at 2 and 4 hrs CRI: 2.5 mg/kg/hr for 42 hours reducing dose gradually	D: 5% Dextrose or 0.9% NaCl I: Normosol-R, Normosol-M, selected drugs†	Precipitation may occur if dilution is too small; reconstituted solution should be used within 48 hours
Metoclopramide 5 mg/mL	Antiemetic; gastrointestinal (GI) stimulant	1–2 mg/kg/day or 0.7–1.4 µg/kg/min or 0.01–0.02 mg/kg/hr (dog) and 0.01 mg/kg/hr (cat)	D: Any IV fluid without calcium I: Sodium bicarbonate; mixing with other drugs should be avoided†	Should be protected from light
Midazolam 5 mg/mL	Anticonvulsant, sedative; similar to diazepam	LD: 0.1 mg/kg (dog) CRI: 0.35 µg/kg/min (dog)	D: 5% Dextrose, 0.9% NaCl I: Mixing with other drugs should be avoided	Does not adsorb to plastics and therefore can be dosed more reliably than diazepam
Morphine 15 mg/mL	Opiate agonist; used in treatment of acute pain	LD: 1–10 mg/hr CRI: 0.01–0.1 mg/kg/hr	D: 5% Dextrose; should be diluted to 0.1–1 mg/mL I: Mixing with other drugs should be avoided†	Lower dose should be used in cats; cats may show CNS excitability
Norepinephrine 1 mg/mL	Potent adrenergic vasopressor; used for short-term blood pressure support	0.05–1.0 µg/kg/min to effect	D: 5% Dextrose or 0.9% NaCl I: Mixing with other drugs should be avoided	Initial systolic pressure should not be raised by >40 mm Hg; extravasation should be treated with phentolamine
Nitroprusside 200 µg/mL	Venous and arterial vasodilator; used in acute, congestive heart failure to treat fulminant pulmonary edema or systemic hypertension	0.5–10 µg/kg/min (dog) 0.1–0.3 µg/kg/min (cat); clinician should start low and increase slowly; BP should be monitored	D: 5% Dextrose; must use with infusion pump only I: Mixing with other drugs should be avoided†	Should be used with extreme caution; over-dose results in cyanide toxicity; should not be used in oliguric patients; solution must be shielded from light
Oxytocin 20 U/mL	Used for enhancement of uterine contractions at parturition	5–10 U over 30 min (dog) 2–5 U over 30 min (cat)	D: 5% Dextrose or 0.9% NaCl I: Mixing with other drugs should be avoided†	Should be used when cervix is open; normal glucose and calcium levels should be ensured first
Pancuronium 1 mg/mL	Neuromuscular blockade as an adjunct to anesthesia or mechanical ventilation	LD: 0.04–0.1 mg/kg CRI: 0.06–0.1 mg/kg/hr	D: 5% Dextrose or 0.9% NaCl, by syringe pump I: Drug insert should be consulted	Cardiovascular and respiratory monitoring must be used
Pentobarbitol 65 mg/mL	GABA-mimetic; used as an anticonvulsant and for chemical restraint during mechanical ventilation	LD: 3–30 mg/kg to effect CRI: 0.2–1 mg/kg/hr	D: 5% Dextrose or 0.9% NaCl I: Mixing with other drugs should be avoided†	Respiratory activity should be monitored; ventilatory support may be required

Phenylephrine 100 mg/mL	Causes vaso-constriction via alpha-adrenergic effects; used to treat hypotension under anesthesia	1–3 µg/kg/min	D: 5% Dextrose or 0.9% NaCl I: Sodium bicarbonate	Extravasation injuries must be treated with phentolamine locally
Potassium chloride 2 mEq/mL	Used to treat serum potassium deficits	In IV fluids: 28–80 mEq/L	D: Any IV fluid I: Diazepam	IV administration should not exceed 0.5 mEq/kg/hr
Potassium phosphate 3 mM/mL phosphorous, 4.4 mEq/mL potassium	Used in correction of hypophosphatemia	0.01–0.03 mM/kg/hr for 6 hr or 0.03–0.12 mM/kg/hr for DKA patients	D: 0.9% NaCl I: Dobutamine, lactated Ringer's solution	50%-75% of potassium supplied using KCl, the rest as KPO4; phospho-rous levels checked every 12 hours in DKA patients, until >2.5 mg/dl
Procainamide 100 or 500 mg/mL	Class IA antiarrhythmics; used in treatment of ventricular arrhythmias	LD: 2–20 mg/kg over 5 min (dog) CRI: 20–50 µg/kg/min LD: 1–2 mg/kg (cat) CRI: 10–20 µg/kg/min (cat)	D: 0.9% NaCl I: Decomposes if admixed with dextrose	Light yellow (but not amber) discoloration does not affect potency; should not be used if dark yellow; stable in fluids for 24 hours
Propofol 10 mg/mL	Short-acting hypnotic	0.05–0.2 mg/kg/min	D: 5% Dextrose I: Should not be mixed with other drugs	Propofol supports bacterial growth; should be used as strict asepsis
Sodium bicarbonate 1 mEq/mL	An alkalinizing agent; used to treat metabolic acidosis; adjunctive therapy in hyperkalemic crises	50% of calculated dose (based on deficit) IV over 4–6 hours	D: 5% Dextrose or 0.9% NaCl I: Mixing with other drugs should be avoided†	Deficit calculation: 0.3 × kg body weight × base deficit
Verapamil 2.5 mg/mL	Calcium channel blocker; used for supraventricular tachyarrhythmias	LD: 0.05–0.15 mg/kg CRI: 2–10 µg/kg/min	D: 5% Dextrose or 0.9% NaCl I: Mixing with other drugs should be avoided	Loading dose not always used
Vitamin B complex (injectable)	Provides B complex supplementation	2–4 mL/L at maintenance fluid rate	D: Any IV fluid I: Sodium bicarbonate	Compatible with IV fluid and TPN solutions

IV, Intravenous; *LD*, loading dose; *CRI*, constant rate infusion; *TPN*, total parenteral nutrition; *GABA*, gamma aminobutyric acid; *CHF*, congestive heart failure; *DIC*, disseminated intravascular coagulation; *BP*, blood pressure; *mM*, millimoles.

* Data compiled from references listed.

† See package insert for details.

Example 2: The clinician must calculate a lidocaine CRI at 60 µg/kg/minute for a 40 kg dog with ventricular tachycardia. The lidocaine will be added to the maintenance fluids, Normosol R in 500 mL bags, running at a rate of 100 mL/hour. To solve this, the clinician would use this formula: µg × kg × minute = µg of drug to be added to a known volume of diluent fluid.

545

To calculate number of minutes each bag will last:

550

500 mL at 100 mL/hour = 5 hours
5 hours × 60 minutes/hour = 300 minutes

To solve the equation:

60 µg (required dose) × 40 kg × 300 minutes = 720,000 µg

To convert µg to mg:

720,000 µg/1000 = 720 mg

To calculate the amount of drug needed per 1000 mL bag, the clinician should divide the amount of drug needed by the concentration of drug being used (in this case, 2% lidocaine or 20 mg/mL):

720 mg/20 mg/mL = 36 mL of lidocaine

Note: 36 mL of Normosol R should be removed from the 1000 mL bag prior to the addition of 36 mL of 2% lidocaine.

Drug manufacturers provide specific diluent recommendations based on drug trials providing stability information. Drugs should be added to small volumes of diluent (usually 60, 100, or 250 mL) and administered separately from the patient's maintenance needs to allow for dose titration, through changes in CRI volume, without affecting the patient's other fluid dose. CRI solutions should always be labeled with the amount of drug added, the date, and the volume of diluent. Solutions should be changed every 24 hours. Drug admixtures should be avoided; when necessary, specific package insert and other recommendations should be consulted.

147.2.3 Drug Delivery Systems

The accurate delivery of parenteral drugs is dependent on the use of sophisticated infusion device technology. The traditional gravity delivery systems (using in-line drip chambers) have been shown to have wide variations in the accuracy of delivery due to factors such as length and diameter of infusion set tubing, distance from the patient, and resistance to flow. These devices are acceptable for intravenous fluid therapy but are not advised for the provision of minute doses of vasoactive drugs. Mechanical devices such as *volumetric infusion pumps* generate positive pressure to achieve the delivery of small and precise volumes. Those that deliver fluid by continuous flow are preferred because the intermittent delivery of vasoactive drugs, particularly when at high concentrations with low flow rates, can cause adverse pharmacodynamic effects. As an example, variable delivery of epinephrine can result in blood pressure variations, whereas variable delivery of nitroprusside may cause toxicity.

Infusion pumps may be classified, according to mechanism of operation, into peristaltic systems, cassette systems, and syringe pump systems. Peristaltic systems (linear or rotary) use a motor-driven mechanism to squeeze the tubing and move fluid toward the patient (Baxter Flo-Gard 6200, Travenol Flo-Gard 6200, Sigma 6000). These systems tend to be less expensive but slightly less accurate than the cassette systems. Cassette systems (Travenol 8000 series, IMED pumps) use an administration set that contains an in-line chamber of a measured volume. Syringe pumps (Baxter 150XL, IVAC 700, Medfusion 3010A) may use motoror nonmotor-driven mechanisms to move the syringe plunger and cause fluid delivery in eithera continuous or intermittent fashion. When an infusion or syringe pump is not available, CRIs may be delivered through a burette type of administration set. This allows the infusion to be limited to a small volume (100 mL). Inherent

inaccuracies exist with this system; for drugs with narrow therapeutic-to-toxic ratios, such as nitroprusside, infusion pump use is essential.

148 CHAPTER • 148 Hyperbaric Medicine

Jennifer J. Devey

Hyperbaric medicine is performed under conditions of greater than 1 atmosphere absolute (ATA) of pressure (Figure 148-1). A specially designed chamber is used, and variable pressures and concentrations of oxygen are delivered based on the condition being treated. In hyperbaric therapy, concentrations of oxygen greater than 21% typically are delivered. However, a recent study examined the use of pressurized air versus pressurized oxygen. Outcomes were similar between the treatment groups, suggesting that pressure, not just oxygen, may be an important factor in hyperbaric oxygen therapy.

148.1 PHYSIOLOGIC EFFECTS

The primary effect of hyperbaric oxygen is to increase the amount of oxygen dissolved in plasma. At 2 ATA and 100% oxygen concentration, the amount of dissolved oxygen in the blood is increased by up to 15 times.

In normoxic tissues, except the heart and lungs, hyperoxic conditions cause vasoconstriction, which helps reduce edema. This in turn improves oxygen delivery to tissues by reducing the barrier to gas diffusion. The decrease in cerebral blood flow also helps reduce intracranial pressure. Decreases in cerebral blood flow have not been noted to be a problem clinically until pressure is greater than 3 ATA. If the tissues are hypoxic, vasoconstriction does not occur.

In neurologic tissue, the increase in oxygen delivery also helps reduce the ischemic penumbra seen in traumatic brain injury and transient ischemic attacks. In traumatic spinal injuries, hyperbaric oxygen has been shown to decrease ischemia, edema, and lactic acidosis and to directly reverse damage associated with bruising.

Hyperbaric oxygen enhances wound healing by promoting the growth of new capillaries, enhancing fibroblast proliferation, increasing collagen formation, and increasing the rate of epithelialization.

Figure 148-1 Pressure conversion table.

1 Bar = 15 psi = 100 kPa = 0.99 atm

psi – pounds per square inch, kPa – kilopascals, atm – atmospheres

Hyperbaric oxygen has been shown to improve immune function, which is impaired in the presence of tissue hypoxia. However, above 2.5 ATA, the immune system is inhibited. Oxygen has a direct bacteriostatic and bactericidal effect that is equivalent to some antibiotics. It is effective against gram-positive and gram-negative bacteria, mycobacteria, and fungi but is most effective in treating anaerobic infections.

Free radicals are produced; phagocytosis is stimulated; and the number of lymphocytes is increased. The levels of immunoglobulin G (IgG) and immunoglobulin E (IgE) decrease, which may be of benefit in the treatment of allergic reactions.

The elasticity of red blood cells is improved and platelet aggregation is reduced, which improves rheology. Hemoglobin synthesis is upregulated after acute blood loss. Hyperbaric oxygen has been used for 25 years as a treatment when blood transfusions have not been readily available.

Hyperbaric oxygen increases the affinity of endorphins for receptor sites, improving analgesia. By improving the microcirculation and decreasing edema, it may help reduce the degree of pain the patient experiences.

Hyperbaric oxygen has been shown to enhance the sensitivity of neoplastic cells to radiation therapy as long as the tumor cells are hypoxic. It does not seem to be effective as an adjunct to radiation therapy if metastases are present. Currently there is no proof that hyperbaric oxygen therapy increases the likelihood of recurrence of the cancer.

148.1.1 **Box • 148-1 Partial List of Conditions Approved for Medicare Reimbursement That Apply to Veterinary Medicine**

Actinomycosis

Birth asphyxiation

Brown recluse spider bite

Cyanide poisoning

Carbon monoxide poisoning

Cerebral edema

Compromised skin graft flaps

Crush injury/compartment syndrome

Diabetic wounds/ulcers

Hypoxic nonhealing wounds

Exceptional blood loss anemia

Frostbite

Gas embolism

Gas gangrene

Near-drowning

Near-hanging

Necrotizing soft tissue infections

Peripheral ischemia

Radiation necrosis

Refractory osteomyelitis

Refractory mycoses

Stroke (transient ischemic attack)

Thermal burns

Traumatic brain injury

148.2 INDICATIONS IN HUMAN MEDICINE

A number of conditions have been approved for U.S. Medicare reimbursement of hyperbaric oxygen therapy. Box 148-1 presents a partial list of these conditions, those that are relevant to veterinary medicine. Based on clinical experience, research findings, and anecdotal reports in human medicine, some other conditions also may respond to hyperbaric oxygen therapy (Box 148-2).

148.3 CONTRAINDICATIONS

The only absolute contraindication for hyperbaric oxygen therapy is untreated tension pneumothorax. Veterinary patients with evidence of any kind of pneumothorax are not placed in the hyperbaric chamber unless a chest tube attached to a relief valve (i.e., Heimlich valve) has been inserted.

Some relative contraindications in human medicine are upper respiratory infections; the presence of pulmonary lesions, even if they are not symptomatic; heart failure; a history of ear or thoracic surgery; and uncontrolled high fever. High fever is a contraindication because of the increased likelihood of seizures; however, this does not appear to be a concern in veterinary medicine. In fact, febrile veterinary patients often experience a reduction in temperature in 100% hyperbaric oxygen environments as long as they are not anxious (see above). Pregnant patients should not receive hyperbaric oxygen because experimental evidence suggests an increased incidence of congenital defects. Epilepsy is not considered a contraindication, but pressure should be kept below 2 ATA.

148.3.1 Box • 148-2 Conditions That May Benefit from Hyperbaric Oxygen Therapy

Cardiac surgery postoperatively

Cranial nerve lesions

Post cardiopulmonary resuscitation

Degenerative myelopathy

Gastrointestinal ulcers

Geriatric vestibular disease

Glaucoma

Head trauma

Hepatotoxins that cause damage after oxidative transformation

Ileus

Methemoglobinemia

Myocardial contusions

Organophosphate toxicity

Osteomyelitis

Pancreatitis

Perianal fistulas

Peripheral neuropathies

Snakebite

Spinal cord injuries or ischemia

148.4 COMPLICATIONS IN HUMAN MEDICINE

Complications primarily relate to oxygen toxicity; however, pressure-related problems, such as sinus pain, middle ear barotrauma, and pulmonary barotrauma, have been reported in human medicine. Complications related to oxygen toxicity are rare, especially if pressure does not exceed 1.5 ATA.

Oxygen-induced seizures can occur in the dog if the pressure exceeds 2.2 to 2.5 ATA. The mechanism is unknown but may relate to the presence of oxygen free radicals, inactivation of nitric oxide, alterations in gamma-aminobutyric acid (GABA), and changes in the levels of biologically active peptides. Seizures normally cease as soon as the oxygen levels drop and/or the pressure decreases. Oxygen-induced seizures are not a contraindication for further treatment; however, the pressure and time of exposure to hyperbaric oxygen should be decreased.

Oxygen-induced lung injury should not be a problem if the lung tissue has sufficient time to recover between episodes. Pulmonary dysfunction has not been noted in humans exposed to prolonged hyperbaric oxygen therapy.

148.5 COMPLICATIONS IN VETERINARY MEDICINE

The complications listed above presumably can occur in all species; however, in more than 5000 hyperbaric treatments, none of them have been observed in clinical veterinary medicine. In veterinary medicine the most common complications are hypothermia in small, sedated, or depressed patients and anxiety, sometimes accompanied by hyperthermia.

148.6 HYPERBARIC CHAMBERS

Chambers can be multiplace or monoplace. High-pressure chambers deliver oxygen concentrations of 100% and pressures up to 6 ATA. The oxygen concentration in lower pressure chambers typically is approximately 30%, and pressures reach a maximum of 1.25 ATA.

Spontaneous combustion, although rare, can occur in hyperbaric chambers that deliver 100% oxygen under pressure. Certain precautions should be taken when using 100% oxygen; electrical devices should not be permitted in the chamber; no nylon should be allowed in the chamber; and the patient must not have an oil-based product on its skin.

Portable hyperbaric chambers compress entrained room air. As a result, the temperature of the room air and the air in the hyperbaric chamber are the same. If the room air is hot, it should be cooled by running the air hose through an ice bath before it reaches the chamber. This prevents overheating of the patient.

Variable levels of oxygen can be provided to patients being treated in lower pressure hyperbaric chambers. When an oxygen source is attached to the chamber, an inspired oxygen concentration of approximately 30% is provided. Alternatively, an oxygen hood can be placed on the patient, in which case the inspired oxygen concentration may be as high as 80%.

148.7 TREATMENT PROTOCOL

Currently no consensus exists on the best regimen for hyperbaric oxygen therapy, although administration within 4 hours of injury appears to be critical in the treatment of neurologic disease. Research indicates that the effects of a single treatment last at least 6 hours.

Current human recommendations are to treat patients for 1 hour at 1.5 to 2 ATA, consisting of 10 minutes of compression, 45 minutes of treatment at the designated pressure, and 5 minutes of decompression time. The time in the chamber is doubled if infections are present.

The author's clinical experience with dogs and cats suggests that pressures of up to 1.25 ATA generally are well tolerated and appear to provide beneficial effects. Treatments last 1 hour and are performed twice daily in the acute stages of the injury or illness and then once daily after the first 3 to 5 days. The twice daily treatments are continued if the patient appears to respond better to treatments at 12-hour rather than 24-hour intervals. With chronic conditions, owners are encouraged to continue treatments two or three times weekly on an outpatient basis if clinical improvement still is noted or if there is concern that relapse will occur if treatment is discontinued.

The vast majority of patients do not object to hyperbaric oxygen therapy, as evidenced by dogs' willingness to walk voluntarily into the chambers repeatedly and by the lack of any outward signs of distress in cats. Anxious patients are provided with anxiolytics. Depending on the patient, this may include narcotics, benzodiazepines, or acepromazine. If any concern arises that the patient is not tolerating the hyperbaric oxygen, the session is discontinued.

Hyperbaric oxygen therapy should not replace approved treatments; however, cats and dogs are affected by a number of disease conditions that appear to benefit from adjunctive therapy with hyperbaric oxygen.

149 # CHAPTER • 149 Nutritional Assessment

Kathryn E. Michel

The purpose of nutritionally assessing a patient is to allow the clinician to answer the question, “Is intervention for this patient necessary?” and to aid the clinician in selecting the most appropriate nutritional intervention for that patient. The process involves evaluating both subjective and objective information regarding the patient and its dietary practices. In addition to aiding in the selection of a suitable diet and feeding management for the patient, it will also help the clinician to anticipate potential problems or complications and to devise strategies to avoid or monitor such developments.

149.1 ## TAKING A DIET HISTORY

The more information that is available about the patient's diet and feeding management, the better the clinician will be able to assess the adequacy of nutrient intake, the suitability of feeding practices, and the urgency for nutritional intervention. At the core of a dietary history is the careful gathering of information that will give an accurate picture of the foods that the patient consumes. Ideally the person who is most responsible for feeding the patient should be questioned; however, it is important to find out who else resides in the household or has regular contact with the patient, including other pets. The patient's caregiver should be questioned about all foods that the patient receives (Box 149-1) and asked whether the information reflects what is typical for this pet, whether changes have occurred, and if so when they happened.

In addition to particulars about the patient's diet, the history should also include information regarding appetite, documented or perceived changes in body weight or condition, level of physical activity, and occurrence of any gastrointestinal (GI) signs. Again, the patient's caregiver should be queried as to whether the information reflects what is typical for this pet or whether (and if so when) changes have occurred. Although it is often the case that a pet owner cannot precisely recount an exact weight change, he or she may have an impression of the period of time over which the change occurred. Rapid weight loss and deterioration in body condition, particularly if associated with muscle wasting, suggests a greater degree of metabolic derangement or reduction in food intake (or both) and greater potential for significant malnutrition than a more gradual loss of weight.

149.1.1 ### Box • 149-1 Information To Be Included In A Diet History

- Commercial pet foods (brand and daily portion; dry foods should be weighed or measured with an 8 oz measuring cup; canned foods should be measured by can size and portion used)
- Commercial treats (brand, size, and frequency of use)
- Table foods or scraps (detailed information about type of food, portion size, and frequency of use)
- Treats for chewing (e.g., rawhide, pig's ears; size and frequency of use)
- Dietary supplements (brand and daily portion)
- Foods used for medication of the patient (type of food, portion size, and frequency of use)
- Pet's access to garbage

- Pet's ability to scavenge or roam

149.2 PATIENT ASSESSMENT

Evaluation of body condition is the chief consideration in the assessment of the animal. Although some sophisticated techniques are currently being used in human patients or in a research setting (e.g., multiple-frequency bioelectrical impedance, dual-energy radiographic absorptiometry (DEXA), neutron activation), they have either not been sufficiently validated in companion animals or do not lend themselves to a clinical setting because of logistic considerations or expense. Body condition scoring, although subjective, is simple to learn, requires no special equipment, and has been shown to be repeatable and consistent among multiple observers.[1] The body condition scoring systems that have been published for companion animals are principally based on characterization of body silhouette and palpation of body fat. These systems are useful, particularly for identification of patients that have an overweight body condition; however, they may misclassify some malnourished patients. It is important to recognize that catabolism of lean body tissue can occur very rapidly and may account for a disproportionate amount of the body mass lost in sick patients. Although the purpose of adipose tissue is to serve as an energy reserve, no analogous reserve of endogenous protein exists. Because all endogenous protein is serving some function, the result of continuous catabolism will eventually have deleterious consequences for the patient. Therefore the process of body condition assessment should include not only the standard evaluation of body silhouette and evaluation of adipose tissue as assessment of energy reserves but also a separate evaluation of muscle mass as a subjective means of assessing lean tissue status. This can be accomplished by palpation of skeletal muscle over the axial skeleton and other bony prominences.

Other aspects of the physical examination of a patient that should be taken into consideration include haircoat quality and skin condition, evidence of peripheral edema or ascites (which may indicate hypoproteinemia), and clinical signs that may indicate specific micronutrient deficiencies such as neck ventroflexion or tetany.

554

555

149.3 SPECIAL CONSIDERATIONS REGARDING ASSISTED FEEDING

No definitive tests are available for establishing a patient's nutritional status. However, based on the information gathered from the patient's medical and dietary history and physical examination (as described previously), the clinician should be able to classify broadly the patient as being well nourished, mildly malnourished, or severely malnourished. The decision whether or not to intervene with some form of nutritional support for a patient has to balance the anticipated benefits with the potential risks and costs of the proposed intervention. Therefore the intent of nutritional assessment should not simply be to diagnose inadequate food intake or malnutrition, but rather to identify patients that are at risk of a poor outcome as a result of their compromised nutritional status. Investigations of human patients have found increased risk of morbidity and mortality associated with various objective markers of nutritional status including hypoalbuminemia, lymphopenia, and attenuated delayed hypersensitivity reactivity. Other investigators have found that clinical assessment of patients based on a carefully performed history and physical examination, as described previously, has predictive value similar to that of objective markers of nutritional status such as serum albumin concentration.[2] Furthermore, investigations of the effect of nutritional support on improving clinical outcome suggest that it is the most significantly malnourished patients that are likely to show benefit from nutritional support.[3]

There has been only limited investigation of the prognostic value of nutritional assessment in veterinary patients. Admission serum albumin concentration has been shown to correlate with risk of poor clinical outcome in critically ill dogs, and elevation of serum creatine kinase activity has been found to be associated with anorexia in

feline patients.[4,5] To date there have not been any investigations of the prognostic value of subjective nutritional assessment or the impact of nutritional support on clinical outcome in companion animals; however, it is not unreasonable to expect results similar to those found in human patients. Therefore it is recommended that patients assessed to be significantly malnourished on presentation or that are at risk of becoming significantly malnourished in the course of their illness due to decreased food intake, malassimilation of diet, or metabolic derangement, should be considered candidates for assisted feeding.

149.4 MONITORING NUTRITIONAL INTERVENTIONS

Once a dietary recommendation has been made, the patient should be reassessed after an appropriate interval of time. The actual timing of reassessment depends on the severity of the patient's illness and the type of nutritional intervention it has received. One should determine whether the prescribed recommendations are being followed if problems with diet acceptance or tolerance are seen, if the desired outcomes have been achieved, or if any adverse events associated with the diet or feeding management have occurred. A thorough nutritional assessment at the outset will often identify potential problems or complications and thereby determine what parameters should be monitored in the patient. At the least, body weight and condition should be reassessed regularly to ascertain that the patient is maintaining, gaining, or losing weight appropriately.

150 CHAPTER • 150 Nutrition of Healthy Dogs and Cats in Various Stages of Adult Life

James G. Morris

Quinton R. Rogers

Andrea J. Fascetti

Although both dogs and cats are classified as carnivores, their nutrient requirements are not identical. The metabolism and nutritional needs of dogs approach those of omnivores, whereas the metabolism of cats is consistent with that of a strict meat-eating mammal. [1–3]

Dogs have the capability to use plant sources for synthesizing taurine, arachidonic acid, and vitamin A from their metabolic precursors, cysteine, linoleic acid, and beta-carotene, respectively. Cats, by contrast, either have diminished enzyme activities for synthesizing these nutrients (taurine and arachidonic acid) from their metabolic precursors, or they do not possess the enzyme (vitamin A). Cats must therefore obtain these nutrients from their diet. Both dogs and cats possess some similar metabolic characteristics such as an obligation to conjugate bile acids with taurine and an inability to synthesize vitamin D. However, the cat digests uncooked starch somewhat better than the dog, so not all evidence is fully consistent with the cat being a strict carnivore and the dog simply being an omnivore.

150.1 FOOD INTAKE AND PALATABILITY

The diet of feral cats is based largely on small mammals, birds, lizards, and insects. When domesticated cats are fed free choice, they eat 10 to 20 meals per day (12 mice per day provide the energy requirement of a normal cat) about equally divided between the light and dark period. Significant breed differences are seen in the feeding behavior of dogs: beagles have feeding patterns similar to cats, whereas basenjis and poodles eat only during the daylight hours. The number of meals can vary widely from 5 to 20. Adult dogs adapt to one meal a day, and cats at maintenance can adapt to a similar regimen. During gestation and lactation, however, performance is enhanced by feeding several times a day or by feeding free choice. During the latter part of gestation and lactation, bitches should be offered food at least twice a day and preferably fed free choice. Both cats and dogs prefer meat-based canned products rather than dry expanded diets, in part owing to the higher moisture content of canned products and in part because blood and fluids contain positive palatability factors. Texture is important; cats and dogs both prefer soft, moist foods to dry, powdery foods. Dogs respond positively to protein, peptides, certain free amino acids, sugar, and mononucleotides, together with certain electrolytes. The response of cats is neutral to protein and sugar, positive to peptides and certain free amino acids, and negative to mononucleotides. Good-quality animal fats enhance palatability for both cats and dogs. Medium chain triglycerides are strongly aversive to cats but not to dogs. Both dogs and cats respond positively to fresh meat extracts, whereas cats but not dogs generally show strong negative palatability to oxidized or rancid fats and breakdown products of trinucleotides or mononucleotides. In summary, cats are more sensitive to adulteration, oxidation, and rancidity in foods than are dogs. Uncooked or cooked meat extracts (broth) are the most palatable natural ingredients to use to enhance the palatability of unpalatable foods for both dogs and cats.

Food intake of cats and dogs fed diets of low or high palatability is quite well controlled. The level at which the animal controls its weight is complex and depends on factors such as genetics (breed and strain), life stage, physical activity, food availability, food palatability, and whether or not the animal is neutered. Both dogs and cats maintain their weight and stay healthy if their diet is complete and balanced, even if the diet has poor palatability. Highly palatable high-fat diets increase the risk for obesity. Nevertheless, dogs and cats control their food intake,

albeit at a higher level of body weight, even when fed highly palatable high-fat diets. It is always easier to prevent obesity by selecting or manipulating the aforementioned factors before obesity occurs rather than to try to limit food intake to affect weight loss. In herbivores and omnivores, food intake is depressed, and strong avoidance of a particular diet is exhibited when animals are fed diets with various nutrient deficiencies or excesses (e.g., deficiencies of thiamine, sodium, phosphate, protein, specific essential amino acids). In most species, including cats and dogs, emetics (e.g., lithium chloride, apomorphine) induce an aversion to the taste of the food just previously eaten. This behavior is called a *learned taste aversion*. In cats there appears to be a neural disassociation between the neural response to the nutrient deficiency and feeding behavior. For those deficiencies and excesses that have been examined (protein deficiency and excess, individual essential amino acid deficiency and excess, sodium deficiency), no learned taste aversions have been demonstrated, despite the fact that food intake may have been depressed.[3,4] Thus palatability may override nutrient metabolic effects in cats, whereas nutrient metabolic effects (caused by nutrient deficiencies and excesses) override palatability effects in herbivores and omnivores (Figure 150-1). It is notable that even though cats do not appear to develop learned aversions to simple nutrient deficiencies or excesses, it has been shown that cats do avoid diets that cause hyperammonemia[5] or metabolic acidosis.[6]

150.2 GENERAL FEEDING RECOMMENDATIONS

Practitioners should advise clients to choose a commercial diet that has passed an Association of American Feed Control Officials (AAFCO) animal protocol test for the particular life stage of the cat or dog. This ensures that the diet has undergone an animal feeding test. An AAFCO nutrient profile label means only that a diet meets a calculated nutrient profile. In most cases it is safest to feed a diet that has passed an AAFCO all-stages protocol. The exception would be if a particular dog or cat has a medical problem; then a specific therapeutic diet should be fed. In selecting an appropriate therapeutic diet, one should always select a diet that has been tested for the intended purpose. If no particular diet has been tested clinically for the particular medical condition, a clinical nutritionist should be consulted for advice or to formulate a balanced homemade diet that is appropriate. It is prudent to check whether a commercial diet (regular or therapeutic) has been properly tested in animals for the intended purpose. No reason exists not to feed a diet that has large built-in safety factors in nutritional requirements, but likewise no reason exists to pay for extra nutrients if they have not been shown to be of extra benefit to the cat or dog. When a diet is complete, balanced, and tested and has been shown to be fully adequate in animals, no reason exists to feed a diet containing even more of one or more essential nutrients. Nevertheless, a paucity of information is available on specific nutrient requirements in adult life stages, including maintenance. There has been considerable research on the nutrient requirements for dogs and cats for growth, because it is the easiest life stage for which to determine requirements. Therefore requirements for growth have been used to formulate requirements during pregnancy. Additional information from epidemiologic evidence and from other species has been used to formulate requirements for maintenance.

150.3 MEETING ENERGY NEEDS

About 80% of the food eaten by mature cats and dogs is used to provide their energy needs. The requirements for protein, minerals, and vitamins can be met in the remaining dry matter. Therefore meeting energy needs is the first consideration in feeding cats and dogs. Energy, unlike individual amino acids, vitamins, and minerals, is not supplied by any single nutrient but is provided by the oxidation of substrates, primarily fats, carbohydrates, and proteins. The energy needs of dogs or cats may be supplied by diets with varying ratios of these three nutrients. The only avenue an animal has for disposal of excess energy is by oxidation to produce adenosine triphosphate or to store the excess energy in the form of adipose tissue. Mature dogs and cats that are in energy balance convert all

the available or metabolizable energy (ME) from food into heat. To calculate the amount of food required by dogs or cats, the ME value of the food should be known.

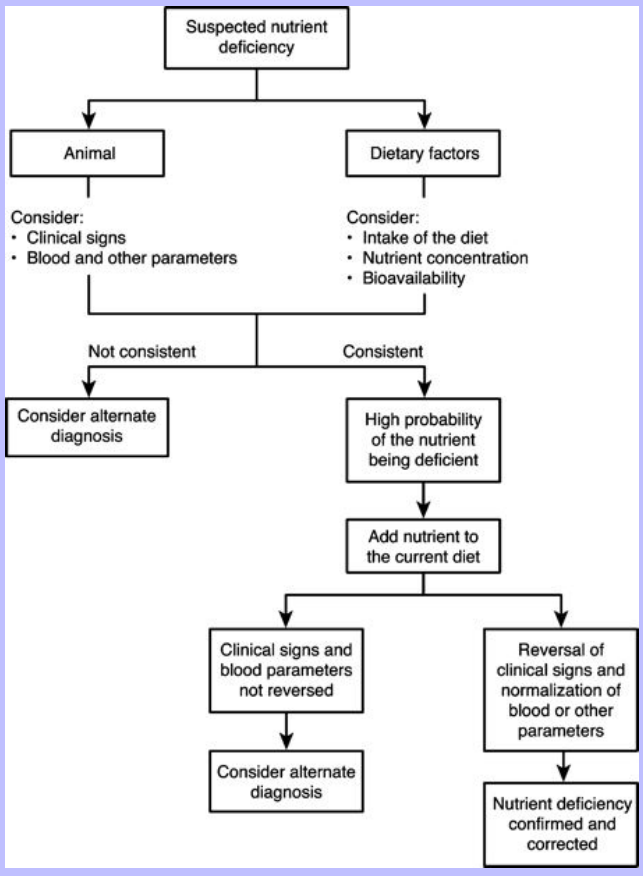
The energy requirements of mature, nonpregnant cats and dogs are not constant but decrease on a unit-body-weight basis with age, which is related to the reduction in general activity with age. As indicated, many individual cats and dogs adjust their energy intake from food to balance their energy needs. However, in some adults, this balance is not maintained, leading either to body weight loss, resulting in catabolism of body energy stores, or to obesity and body weight gain owing to excessive energy intake.

The maintenance energy requirements of adult cats and dogs may be estimated from formulas relating ME requirements to body weight. Because mature dogs have about a fiftyfold range in body weight, and because ME requirements per unit of body weight decrease with body weight, formulas generally include some power function of body weight (e.g., body weight raised to three-fourths power). A common linear formula used for dogs is ME = 30 W + 70, and an exponent formula is ME = 132 $W^{3/4}$, where W is body weight in kilograms and ME is kilocalories per day. The first equation approximates the relationship for small dogs such as beagles but overpredicts energy requirements for large breeds. Because the body-weight range of adult cats is much less than that of adult dogs, a power function is not used with cats. The formula ME = 80 W has been used for active cats and ME = 70 W for inactive cats.

556

557

Figure 150-1 Algorithm for solving a nutrient deficiency in an adult dog or cat.



Although these formulas are useful starting points, they are not absolute requirements because considerable individual animal variation exists. It has been shown that a large variation exists in the prediction interval of maintenance energy requirement.[8] However, when enteral or parenteral nutritional support is necessary, a requirement estimate must be made. Similarly, when a weight reduction program is undertaken, an estimate of maintenance energy requirements is desirable. All adult cats and dogs that are voluntarily consuming food should be fed relative to their body condition and not by a formula. If an adult dog or cat is fed free choice and becomes obese, either the amount of food offered or the energy density (available caloric density) of the food should be reduced. When an adult cat or dog is not maintaining body weight, either more food or a more palatable food should be fed to increase intake or a diet of a higher caloric density should be fed (or both should be done).

Pregnancy causes a demand for energy greater than normal adult maintenance requirements. Different responses to pregnancy occur in the ingestive behavior of bitches versus queens, even though the length of gestation is similar. Queens increase food intake soon after conception and have an almost linear increase in body energy stores with duration of gestation. In contrast, bitches normally do not increase food and energy intake until the latter stages of pregnancy. Queens and bitches in normal body condition may be given food free choice during pregnancy to allow for the increase in body tissue that will be mobilized during lactation and by fetal energy demands. Whereas the latter stages of pregnancy increase energy requirements by about a third, lactation places a huge demand on the bitch and queen and can result in energy intakes three to four times above maintenance. Depending on the number of kittens or pups, queens or bitches sustain a loss of body weight during lactation. This tissue loss should be largely the tissue gained during the prepartum period; with a good diet and normal litter size the weaning body weight of the mother should not be less than the body weight at conception.

557

558

150.4 PROTEINS AND AMINO ACIDS

Proteins are added to diets to provide essential amino acids and nitrogen. Nitrogen requirements are usually expressed as the crude protein requirement, because crude protein is defined as the quantity of nitrogen times 6.25. Nitrogen is used for the biosynthesis of dispensable amino acids, heme, purines, pyrimidines, and so forth. Both essential and dispensable amino acids are necessary at the cellular level for protein synthesis. Several amino acids are precursors for hormones and neurotransmitters. If the amino acid and crude protein requirements are known for each life stage, the clinical nutritionist can formulate a diet using amino acid composition tables for particular proteins and ensure that both essential amino acid and nitrogen requirements are met. However, a weakness of diet formulation using nutrient composition tables is that the bioavailabilities of amino acids and nitrogen from food sources are usually not known, or the effect of processing on the particular food (or food combinations) is not known. The most accurate way to tell if the diet is adequate in protein is to evaluate plasma amino acid concentrations during the absorptive state after feeding a particular diet. Amino acid patterns can be used not only to verify that essential amino acid requirements have been met but also to diagnose various nutritional problems (e.g., protein-energy malnutrition, essential amino acid deficiency) and metabolic problems (e.g., liver or kidney disease).

Carnivores have no problem meeting their protein or amino acid requirements if they eat other animals, because the body composition of various animals is quite similar and is high in good-quality protein. Nutritional problems arise only if a client attempts to feed a carnivore a vegetarian diet or a diet that has poor-quality ingredients (e.g., by-products that are high in collagen, such as skin and bone) or products that have been excessively processed. Quality control of ingredients in pet foods is a problem in the pet food industry, because large quantities of animal by-products do not always have a constant composition; thus these by-products may have variable digestibilities and bioavailabilities for nitrogen and amino acids. Specific amino acid deficiencies or excesses can cause a variety of problems, such as cataracts, dermatitis, hair loss or reddening of black hair or both, irritability, neurologic

deficits, hyperammonemia, fatty liver, low glutathione, and emesis. After reviewing the literature and using our experience in feeding dogs and cats, we have developed an estimate of dietary nutrient allowances (Table 150-1). These allowances include an approximate 25% to 50% in excess of the minimal requirement to allow variation in bioavailability. Our estimate of minimal requirement is undoubtedly high for several of the amino acids, because so many data are missing, especially for the adult life stages. Nevertheless, these values may be used as guidelines until more refined data are available. It is possible, using diet composition tables, that these recommendations may be too low owing to poor-quality ingredients with low digestibility coefficients. Most cat and dog foods are formulated to meet or exceed these recommendations. Major pet food companies have competent nutritionists who take digestibility and bioavailability values into account in formulating diets, and most of the major diets have been tested. Therefore veterinarians should be confident in recommending any pet food that has passed the AAFCO feeding protocol for the life stage in question. The bottom line is simple for adult dogs and cats: feed a commercial diet for the appropriate life stage from a reputable company. The only other safe course is consultation with a small animal nutritionist to attempt to evaluate a diet or to formulate a homemade diet. The latter is not recommended because of the difficulty in predicting bioavailability of ingredient nutrients and the difficulty in getting good compliance in making and feeding such a diet.

Table • 150-1 Suggested Nutrient Allowances* for Adult Dogs and Cats at Maintenance (Nutrient Per 1000 kcal of Dietary Metabolizable Energy)

NUTRIENT	UNIT	ADULT DOG	ADULT CAT
Protein†	g	37.5	75.0
Arginine	g	1.43	3.13
Histidine	g	0.54	0.90
Isoleucine	g	1.05	1.75
Leucine	g	1.80	3.75
Lysine	g	2.25	3.00
Methionine +cysteine	g	1.50	2.75
Methionine	g	0.75	1.50
Phenylalanine +tyrosine	g	2.10	2.50
Phenylalanine	g	1.05	1.25
Threonine	g	1.20	2.00
Tryptophan	g	0.35	0.50
Valine	g	1.28	1.75
Calcium	g	1.6	1.2
Phosphorus	g	1.2	1.2
Potassium	g	1.2	1.25
Sodium	g	0.40	0.40
Chloride	g	0.20	0.20
Magnesium	g	0.11	0.08
Iron	mg	20.0	20.0
Copper	mg	0.8	1.1
Manganese	mg	1.4	1.1
Zinc	mg	9.7	11.0
Iodine	mg	0.16	0.07
Selenium	mg	0.03	0.02
Vitamin A (retinol)	mg	0.3	0.21
Vitamin D (cholecalciferol)	g	2.75	2.6
Vitamin E (alpha-tocopherol)	mg	6.1	7.0
Vitamin K	g	—	2 1.0
Thiamine	mg	0.3	1.1
Riboflavin	mg	0.7	0.9
Pyridoxine	mg	0.3	0.9
Niacin	mg	3.0	10.0
Pantothenic acid	mg	2.7	1.0
Folic acid	mg	0.54	0.17
Vitamin B_{12}	µg	7.0	4.0
Biotin	µg	—	15.0
Choline	mg	340.00	500.00

* These values are not minimal nutrient requirements, but nutrient allowances. Requirements have been increased to accommodate variation in digestibility and bioavailability of nutrients in natural foods and individual animal variation.

† For a protein of good quality. The requirement for protein and amino acids needs to be increased for proteins of lower quality or lower digestibility.

150.5 MINERALS AND VITAMINS

Adult cats and dogs require the same minerals and vitamins that are essential to growing kittens and puppies. Although the requirements for growing kittens and puppies are fairly well defined, those for adults are not known with the same precision. The dietary concentration for growth satisfies adult requirements, even though the food intake of adults on a unit-body-weight basis is less than that during growth. The function and clinical role of vitamins have been reviewed.[8]

558
559

150.5.1 Minerals

Mineral requirements for adult cats and dogs for maintenance (expressed per 1000 kcal dietary ME) are given in Table 150-1. These requirements are based on published values[9,10] with updated information. Expression on an equivalent energy basis shows that the requirements of adult cats and dogs are similar. The requirements given in Table 150-1 are for minerals with a high bioavailability, such as from mixtures of the salts of these minerals or from bone. Applying these values to practical diets requires bioavailability values to be taken into account. Although these have not been determined in cats and dogs, values originating in other simple-stomached species give useful approximations. The bioavailability of calcium, phosphorus, and magnesium from plant sources is considerably less than that from mineral salts or bone and should be discounted by 50%. In contrast, sodium, potassium, and chloride are readily exchangeable, and no adjustments are necessary concerning their source.

Bioavailability of trace elements, especially as they pertain to cats and dogs, is not known, but observations indicate that the availability of zinc and copper in diets containing high proportions of plant products is compromised. Zinc deficiency has not been uncommon in dogs fed some of the lower-quality dry diets containing a high proportion of plant products. Clinical signs of copper deficiency have been reported in newborn kittens from queens given diets containing copper oxide as a supplementary source of copper. Reproductive performance of the queens was also reduced. The requirements for many of the major minerals (e.g., calcium, potassium, sodium) increase greatly in lactation. However, because food intake is also increased about twofold, the percentage in the diet need not change.

Diagnosis of mineral deficiencies should be based on specific clinical signs, blood, plasma, or tissue concentrations for the species, as well as on reversal of clinical signs after supplementation with the specific mineral while the cat or dog is maintained on the same diet.

150.5.2 Vitamins

Vitamin requirements of adult cats and dogs expressed based on 1000 kcal of ME are given in Table 150-1. The values are based on published data[9,10] that have been modified when newer information was available. For the fat-soluble vitamins A, D, and E, the requirements are similar for adult cats and dogs. Cats, unlike dogs, are unable to use beta-carotene as a precursor for retinol, so they depend on preformed vitamin A in the diet. The values for vitamin A and D are in excess of minimal requirements, and further supplementation in normal animals is unwarranted. Neither cats nor dogs are capable of synthesizing vitamin D from ultraviolet (UV) light.[11] Although vitamins A and D are regarded as the most toxic of all the vitamins when given in excess, adult cats can tolerate large excesses (50 times requirement) of these two vitamins with no discernible deleterious effects. In normal cats and dogs, in contrast to most other animals, large concentrations of retinyl esters occur in plasma. Requirements for vitamin E are a function of the total polyunsaturated fatty acids

(PUFAs) in the diet. Because cats frequently consume diets high in PUFAs, the requirement to prevent steatitis in cats is higher than that for dogs that are subjected to lower dietary inputs of PUFAs. Both cats and dogs require an exogenous source of vitamin K, but intestinal synthesis appears to be adequate to supply this need in dogs. When cats are fed some high-fish diets, they have a prolongation of clotting time and require supplemental vitamin K.

In contrast to the fat-soluble vitamins, the requirements for the water-soluble vitamins for cats versus dogs are different. Cats have a higher requirement than dogs for thiamine (vitamin B_1) and are exposed to dietary ingredients that often contain both thiaminases (e.g., fish) and to canned diets that have sustained extensive processing, causing loss of thiamine. As thiamine stores are rapidly exhausted, thiamine deficiency can readily occur in cats given deficient diets. Cats, unlike dogs, are unable to use tryptophan as a precursor for niacin synthesis, so niacin is an absolute essential dietary nutrient for cats. Niacin is normally obtained from foods by hydrolysis of nicotinamide adenosyl dinucleotide (NAD) and nicotinamide phosphodinucleotide (NAPD) in the gut. Meats contain high levels of these nucleotides and thus are a principal source of this vitamin.

The published vitamin requirements[9,10] for growing kittens and puppies appear to satisfy the requirements of mature cats and dogs. However, in applying these values, it is necessary to take into consideration the bioavailability of the vitamin and its stability in the product. The bioavailability of the fat-soluble vitamins is high in the absence of most fat malabsorption syndromes, whereas the bioavailability of most of the B vitamins in natural products is variable and can be quite low.

150.6 TAURINE

Taurine, a beta-sulfur amino acid, occurs in all animal cells and is virtually the sole conjugate of the bile acids in cats and dogs. Taurine is synthesized de novo by dogs and cats from the sulfur amino acids cysteine and methionine. Although cat diets contain a higher level of sulfur amino acids than do dog diets, the rate of taurine synthesis by cats is low; cats given a low-taurine diet are readily depleted of this amino acid. This very low rate of taurine synthesis in cats is a consequence of low activities of two enzymes in the pathway of synthesis. Taurine depletion is associated with a wide range of clinical conditions, including feline central retinal degeneration, reversible dilated cardiomyopathy, reproductive failure in queens, and developmental defects and growth retardation in kittens. The amount of dietary taurine required for cats to maintain adequate blood concentrations varies twofold with the type of diet. For expanded (dry) diets, 1250 mg taurine/kg dry matter is adequate. Canned diets, which promote higher intestinal degradation of taurine exposed in the enterohepatic circulation, require 2500 mg/kg dry matter to maintain blood concentrations in the normal range.

Until recently, diet-associated taurine deficiency in dogs has not been recognized. However, low blood taurine concentrations and dilated cardiomyopathy (DCM) has recently been identified in dogs that do not have a genetic predilection to this disease. A common finding among the cases was the consumption of commercial dry diets containing lamb meal, rice, or both as the primary ingredients. Cardiac parameters and blood taurine concentrations improved with treatment and taurine supplementation. Dogs that survived longer than 1 year were able to be removed from all cardiac mediations except taurine, suggesting that these were not typical cases of DCM. Suggested mechanisms for taurine deficiency in these dogs were considered to be (1) insufficient synthesis of taurine, (2) extraordinary loss of taurine or its precursors in urine, (3) extraordinary gastrointestinal (GI) loss of taurine in bile acid conjugates (as found in cats), or (4) a reduction in protein digestibility. Based on clinical findings, blood taurine concentrations, and common diet histories, it appears that the consumption of diets with inadequate or unavailable sulfur amino acid taurine precursors, plus rice bran increasing GI loss, results in taurine deficiency and low blood taurine concentrations in these dogs. The low plasma taurine concentrations can lead to the development of abnormal cardiac function and DCM.

150.7 ESSENTIAL FATTY ACIDS

The diets of healthy dogs and cats, like those of other animals, must contain polyunsaturated fatty acids (PUFAs). Because these fatty acids cannot be synthesized de novo by animals, they are designated as essential fatty acids (EFAs). Dogs require two EFAs in the diet: linoleic acid C18:2 n-6 and linolenic acid C18:3n-3. The letter followed by the number (e.g., n-6 or ω-6, n-3 or ω-3) refers to the location of the first double bond in the fatty acid from the methyl (or omega) end of the fatty acid. Animals cannot insert double bonds further than 9 carbons from the carboxyl end of a fatty acid. In addition to linoleic and linolenic acids, cats under certain conditions may require arachidonic acid, a member of the n-6 family of fatty acids in the diet. The activity of the hepatic delta-6-desaturase enzyme required in one of the pathways for the synthesis of arachidonic acid from linoleic acid is low in cats. This limited activity appears to be sufficient for growth and reproduction in male cats (where the testis also has delta- 6-desaturate activity) but may be inadequate for sustained reproduction in queens. Other fatty acids, particularly those of the n-3 series, may also limit reproduction in queens.

Fatty acids function as precursors of eicosanoids, which include prostaglandin, leukotrienes, and thromboxanes. These extremely active biologic compounds have both paracrine and endocrine activity. As a group the eicosanoids of the n-6 series tend to be involved in a more proinflammatory role, whereas those of the n-3 have an anti-inflammatory or only a mildly inflammatory role.

Of the EFAs, the quantitative requirement of cats and dogs is greatest for linoleic acid. A deficiency of linoleic acid results in hyperkeratosis of skin, fatty degeneration of the liver, and degeneration of the testis. In addition, increased water loss through the skin occurs. Cats and dogs require about 1% to 2% of the calories as linoleic acid to prevent clinical signs of deficiency, though higher levels of total fat in the diet may result in better coat condition. The n-3 fatty acid, linolenic acid, occurs in high concentration in some plant oils such as linseed (flaxseed) oil, and higher homologues of this fatty acid occur in animal fats, particularly marine oils such as herring and tuna. In cats, the production of these higher n-3 homologues also appears to be limited, which may contribute to the poor reproductive performance of queens given some vegetable fat diets.

Clinical signs of arachidonate deficiency in cats are associated with eicosanoid dysfunction and include defective reproduction in queens and changes in blood platelet aggregation. The requirement of cats for arachidonic acid has not been defined but appears to be of the order of 200 mg/kg dry matter. Arachidonate in natural diets comes from animal tissue membranes. Recently a fungal source of arachidonate has become commercially available, so it is possible to add this fatty acid to diets for cats without the inclusion of animal fat.

150.8 OTHER NUTRIENTS AND NUTRACEUTICALS

Choline is often included among the “essential” vitamins because it supplies labile methyl groups. Methionine and betaine can also supply methyl groups. A lack of total methyl groups in the diet leads to fatty liver because of an inability to mobilize hepatic fat.

Ascorbate, or vitamin C, is synthesized de novo by dogs and cats from glucose, and no substantiated evidence exists (except anecdotal reports in liver disease) to indicate that dogs or cats benefit from the addition of ascorbate to the diet. In contrast, some breeds of dogs have a limited capacity to synthesize adequate carnitine and benefit from its supplementation. Synthetic antioxidants are frequently added to human and animal diets to prevent lipid peroxidation during storage. Substantial evidence contraindicates the consumption of lipid peroxides. It is debatable whether these synthetic antioxidants are deleterious when used at the recommended concentrations in the diet. Natural antioxidants such as alpha-tocopherol, though less effective than the synthetic antioxidants, can

also be used. A number of human foods such as onions and chocolate cause adverse effects in cats and dogs, respectively; thus some human foods should not be fed to cats and dogs indiscriminately. Food faddism in human nutrition has resulted in malnutrition, toxicities, and deficiencies.[12] These same practices occur in dog and cat nutrition and should be avoided.

151 CHAPTER • 151 Neonatal and Pediatric Nutrition

Johnny D. Hoskins

The nutritional requirements, feeding, and care of puppies and kittens from birth to early adulthood are substantially different during their different stages of growth. The growth phase is a critical time in the life of a puppy or kitten; some will fail to grow to the size determined by their hereditary factors unless they consume appropriate food of adequate quality.

151.1 FEEDING THE PUPPY

Healthy puppies, during the first 2 to 3 weeks of life, should only eat and sleep. Nursing should be vigorous and active, with each puppy receiving sufficient milk from its mother. If the mother is healthy and well nourished, the puppy's nutritional needs for its first 3 to 4 weeks of life should be provided completely by her. Indications that the puppy is not receiving sufficient milk are constant crying, extreme inactivity, or failure to achieve weight gains in accordance with thegeneral guidelines that a puppy should gain 1 to 2 g/day/lb (2 to 4 g/day/kg) of anticipated adult weight (or at least 10% gain per day).[1] For example, if the adult dog is expected to weigh 30 lb, as a puppy it should gain 30 to 60 g/day during its first 5 months of life.

The transition from mother's milk to solid food should be a gradual process beginning at about 3 weeks of age (4 weeks of age for toy breeds); however, if necessary, supplemental feeding may be started as soon as the puppy fails to showsufficient weight gain. During the changeover to solid food, the puppy can be offered a thick, gruel-like mixture of good-quality puppy food designed for growth and water (one part dry food blended with three parts water, or two parts canned food blended with one part water). To get the puppy eating, the gruel is placed in a shallow food dish, the puppy is encouraged to lap the gruel by touching its lips to the food, or the feeder can put a finger in the gruel and then into the puppy's mouth. It can also be force-fed using a commercial dosing syringe. Once the puppy accepts the gruel, the amount of water is gradually reduced until it is omitted.

By 6 weeks of age, the puppy should be receiving at least 25% of its requirements from the weaning diet. The puppy may be permanently separated from the mother as soon asit learns to eat readily and drink satisfactorily. Most puppies are completely weaned at 7 to 8 weeks of age, depending somewhat on size and breed. Early weaning and separation from littermates, prior to 6 weeks of age, however, can cause malnutrition or numerous behavioral problems later in life. Because of this, complete weaning should not be attempted until puppies are at least 6 weeks old and close humancontact has been established.

Feeding the weaned puppy should always be directed to attaining the appropriate growth rate for the breed.[1] Instead of making food available to the puppy at all times (free-choice feeding), time-limited meal feeding is recommended. At each feeding, the puppy should be given 15 to 20 minutes to eat all that it wants; then the remaining food should be removed. From the time of weaning to 4 to 6 months of age (9 months for giant breeds), puppies are best fed at least three timesa day at regular intervals. Thereafter, puppies should be fed twice a day on a regular schedule.

Some large and giant breeds of dogs (those over 30 kg body weight at maturity) have the genetic capacity to grow rapidly and will do so if provided with a food that meets or exceeds their nutrient and energy needs. However, a rapid growth rate is not compatible with normal skeletal growth and may result in certain types of developmental bone disease.[2,3] Beginning at weaning and continuing until they reach maturity, large and giant breeds of dogs should be fed for a moderate growth rate. This can be accomplished by limiting food intake or, even better, by

feeding a growth-formulated puppy food for large and giant breeds. If osteochondrosis or hypertrophic osteodystrophy occurs, nutritional management should be aimed at reducing caloric intake by decreasing the amount of food that is fed or feeding a growth-formulated puppy food for large and giant breeds.

151.2 FEEDING THE KITTEN

Healthy kittens, during their first 4 weeks of life, should nurse vigorously and actively. If the mother is healthy and well nourished, the nutritional needs of the kittens during this time should be filled completely by her. Each kitten should receive sufficient milk from its mother. Kittens not receiving sufficient milk cry constantly, are restless or extremely inactive, or fail to achieve the expected weight gain of 10 to 15 g/day.[1]

Kittens should be encouraged to begin eating solid food at 4 weeks of age. At this time, the kitten can be offered a thick, gruel-like mixture of good-quality kitten food designed for growth and milk or water (one part dry food blended with three parts milk, or two parts canned food blended with one part milk). The gruel is fed to kittens from a shallow bowl or force-fed by using a commercial dosing syringe. The feeder can encourage the kitten to eat the gruel by smearing some of the gruel on the kitten's lips, being careful not to get any in the nose, or placing a finger in the gruel and then into the kitten's mouth. This usually encourages the kitten to eat from a bowl at an early age. Once the kitten is eating the gruel well, the amount of milk or water in the gruel is gradually reduced until the kitten is consuming only solid food. The kitten may be permanently separated from the mother as soon as it learns to eat readily and drink satisfactorily. Most kittens are completely weaned at 6 to 8 weeks of age. Early weaning andseparation from littermates before 6 weeks of age can resultin behavioral problems such as slowness to learn and more suspicious, cautious, and aggressive actions.[4]

Food given to weaned kittens should be one specifically formulated for growth. Feeding between 3 to 3.5 oz of dry food per day or 8 to 10 oz of canned food per day usually meets the growth requirements of most kittens. Becausethe kitten's eating habits are still in the formative stage after weaning, it is important that easily digested, high-quality, calorically dense food is provided. Cow's or goat's milk is often fed to kittens after weaning and is a good food, provided that it does not cause diarrhea. Milk should never be given in place of fresh water.

561 562

Kittens should be fed all the food they will consume. Excessive caloric intake and excessively rapid growth rate are seldom problems in growing kittens. Most kittens are not voracious. When food is always available, they nibble at it frequently. Kittens fed unlimited amounts of food (free-choice feeding), regardless of the form of food (dry or canned), eat every few hours. Free-choice feeding, or at least three-times-a-day feeding, is preferred during growth.

At 12 weeks of age the kitten's energy needs are three times greater than those of an adult cat, or more than 200 kcal/kg of body weight. As kittens mature past 6 months of age, their growth rate slows and their food needs decrease. Their energy needs are still greater than adult cats, or approximately90 kcal/kg of body weight.

151.3 REARING NURSING PUPPIES AND KITTENS

Newborn puppies and kittens are unable to effectively control their body temperature.[5] During their first 4 weeks of life, they gradually progress from being largely poikilothermic to being homeothermic. That is, for the first week of life their body temperature is directly related to the environmental temperature, and a steady ambient temperature of 30° to 32° C (86° to 90° F) is needed. Over the next 3 weeks, the ambient temperature can be gradually lowered to 24° C (75° F). Humidity should be maintained at 55% to 60%. It is equally important that sudden changes of environmental conditions be avoided.

The most obvious alternative to a mother rearing her own young is for another nursing mother to act as a foster mother. If a foster mother is not available, it is necessary to hand-feed the puppies or kittens a replacement food that is a prototype of nutritive substance formulated to meet the optimum requirements of the puppy or kitten. Mother's milk is the ideal food. Various modifications of homemade and commercially prepared formulas simulating mother's milk have been used with good success. [5–7] Commercially prepared formulas are preferred, because they closely compare to mother's milk. These formulas generally provide 1 to 1.24 kcal of metabolizable energy per milliliter of formula. The caloric needs for most nursing-age puppies and kittens are 22 to 26 kcal per 100 gof body weight. Therefore the average puppy or kitten should daily receive approximately 13 mL of formula per 100 g of body weight during the first week of life, 17 mL of formula per 100 g of body weight during the second week, 20 mL of formulaper 100 g of body weight during the third week, and 22 mL of formula per 100 g of body weight during the fourth week. These amounts of formula should be given in equal portions three or four times daily. For the first 3 weeks of life, theformula should be warmed before each feeding to about100° F (37.8° C) or to a temperature near the animal's body temperature.

After each feeding, the abdomen should be enlargedbut not overdistended. When a formula is used, less thanthe prescribed amount should be given per feeding for the first feedings. The amount should then be gradually increased to the recommended feeding amount by the second or third day. The amount of formula should then be increased accordingly as the puppy or kitten gains weight and a favorable response to feeding occurs. Puppies should gain 1 to 2 g/day/lb (2 to 4 g/day/kg) of anticipated adult weight for the first5 months of their lives. At birth the kitten should weigh 80 to 140 g (most weighing around 100 to 120 g) and gain 50 to 100 g weekly.[1]

When preparing formula the clinician should always follow the manufacturer's directions for its proper preparation and keep all feeding equipment scrupulously clean. A good way of handling prepared formula is to prepare onlya 48-hour supply at a time and divide this into portions required for each feeding. Once formula is prepared, it is best stored in the refrigerator at 4° C.

The easiest and safest way of feeding prepared formulato nursing-age puppies and kittens is by nipple bottle, dosing syringe, or by tube.[1] Nipple bottles made especially for feeding orphan puppies or kittens or bottles equipped with preemie infant nipples are preferred. When feeding with a nipple bottle, the clinician or other staff member should hold it so that the puppy or kitten does not ingest air. The hole in the nipple should be such that when the bottle is inverted, milk slowly oozes from the nipple. It may be necessary to enlarge the nipple hole with a hot needle to get milk to ooze from the bottle when inverted. When feeding, a drop of milk should be squeezed onto the tip of the nipple and the nipple shouldbe inserted into the animal's mouth. Milk should never be squeezed out of the bottle while the nipple is in the animal's mouth; doing so may result in laryngotracheal aspiration of the milk into the lungs. In addition, prepared formula should never be fed to a puppy or kitten that is chilled or that does not have a strong sucking reflex. Only when the sucking reflex is present should feeding with nipple bottle be attempted.

Tube feeding is the fastest way to feed orphaned puppies or kittens. Most owners can do it easily with a little training. The following may be used: a No. 5 French (F) infant feeding tube for puppies or kittens weighing less than 300 g, a No. 8 to 10 F infant feeding tube for puppies or kittens weighing over 300 g, or an appropriately sized, soft, male urethral catheter. Once weekly, the feeding tube should be clearly marked to indicate the depth of insertion to ensure gastric delivery (that is, the distance from the last rib to the tip of the nose can be measured and marked off on the feeding tube as a guide). The animal should never be fed into the distal esophagus. When feeding, a syringe should be filled with warm, preparedformula and fit it to the feeding tube. The clinician or staff member should be sure to expel any air in the tube or syringe. The animal's mouth should be opened slightly and, with the animal's head held in the normal nursing position, the feeding tube should be gently passed to the marked

area. If an obstruction is felt, or coughing occurs, before reaching the mark, the tube should be assumed to be in the trachea. If this does not happen, the prepared formula should be slowly administered over a 2-minute period to allow sufficient time for slow filling of the stomach. Regurgitation of formula rarely occurs; but if it does, the feeding tube should be withdrawn and feeding interrupted until the next scheduled meal.

A vital aspect of tending orphaned puppies and kittensis to simulate after feeding, the mother's tongue action onthe anogenital area, which provokes reflex micturition and defecation. Application of this stimulus has to be taken over by the person tending the puppies or kittens. The clinician can achieve the necessary result by swabbing the anogenital area with moistened cotton or dry, soft tissue paper to manually stimulate the reflex elimination. It is sometimes possible to effect the same response simply by running a forefinger along the abdominal wall. This stimulation should be regularly provided after each feeding using nipple bottle or tube. After they reach about 3 weeks of age, puppies and kittens are usually able to relieve themselves without simulated stimulation.

Most puppies and kittens benefit from gentle handling before feeding to allow for some exercise and to promote muscular and circulatory development. In addition, at least once a week the orphaned puppy or kitten should be washed gently with a soft moistened cloth for general cleansing of the skin, simulating the cleansing licks of the mother's tongue.

152 CHAPTER • 152 Nutrition-Related Skeletal Disorders

Herman A.W. Hazewinkel

152.1 INTRODUCTION

Some skeletal diseases can be linked to unbalanced nutrition (alimentary hyperparathyroidism, rickets). The incidence of many hereditary, developmental skeletal diseases (hip dysplasia [HD], osteochondrosis) may be enhanced by inappropriate nutrition. More than 99% of body calcium (Ca) is stored in the skeleton, giving it rigidity. The extracellular Ca concentration ($[Ca^{2+}]$) is also of paramount importance for different cellular, contractive, and enzymatic processes. Plasma $[Ca^{2+}]$ is maintained in a relatively narrow range with the aid of physiochemical processes: increase in $[Ca^{2+}]$ causes Ca transport to cell organelles, storage of Ca in the labile Ca-pool of bone, and increased glomerular Ca excretion with fine tuning by a variety of regulators, including the calciotropic hormones parathyroid hormone (PTH), calcitonin (CT), and vitamin D (vitD). These hormones have direct or indirect actions (or both) on the skeleton, kidneys, and gut[1] (Figure 152-1). The skeleton includes both bone and cartilage cells and their matrix. Appositional growth of bones occurs by osteoblasts originating from the periosteum; growth in length takes place via endochondral ossification, whereas bone remodeling is controlled by osteoclasts.

152.2 ALIMENTARY HYPERPARATHYROIDISM

Chronic insufficient Ca intake or absorption results in increased PTH synthesis and secretion. PTH, in turn, increases osteoclast activity (deliberate Ca and phosphorous [P] from the skeleton), increases calcitriol synthesis in the kidney (thus increasing intestinal Ca and P absorption), and decreases P reabsorption from renal tubuli (thus causing hyperphosphaturia)[2,3] (see Figure 152-1). Consequently, hyperparathyroidism will normalize the extracellular $[Ca^{2+}]$. When the increase in Ca absorption in the intestine is not covering the daily requirements, the skeleton is the only remaining source of Ca. Ca will be resorbed at the endosteal surface of the diaphyses and in the areas of cancellous bone. Mineralization of osteoid and cartilage will be undisturbed.[4,5]

152.2.1 Clinical and Radiologic Examination

The most commonly affected dogs and cats are young and raised on foods that are extremely low in Ca content. Usually this includes meat or by-products. Therefore this metabolic bone disease is sometimes referred to as “all-meat syndrome.” However, food of low quality binding Ca to phytate may also cause chronic Ca deficiency, especially in young dogs of large breeds. Affected dogs and cats are reluctant to stand and walk and can even be paralyzed due to spinal compression by pathologic fractured vertebrae. Blood investigation will not reveal hypocalcemia, although elevated PTH and calcitriol ($1,25[OH]_2$vitD) levels can be detected [3,5] (see Figure 152-1). Radiographs may reveal thin cortices, wide medullary cavities, folding (green stick) fractures, normal height of growth plates with relatively white metaphyseal borders, as well as compression fractures of cancellous bone of epiphyses and vertebrae.[4,5]

152.2.2 Differential Diagnosis

Ca deficiency can be complicated with vitD deficiency when solely lean meat (which is low in Ca and vitD) is fed. Bone disease due to an inborn error may resemble alimentary hyperparathyroidism, including osteogenesis imperfecta, mucopolysaccharidosis, and other rare diseases.

152.2.3 Therapy

It is extremely important to prevent more pathologic fractures (especially of the vertebrae). The skeleton is too fragile for bandages, splints, or implants. Analgesics will facilitate early mobility, which is not desirable. Changing to a balanced diet with a Ca content up to 1.1% on a dry-matter basis will allow the skeleton to mineralize within 3 to 4 weeks, because almost 100% of the ingested Ca will be resorbed due to the hyperparathyroid-induced high calcitriol levels.[3] Extra Ca as Ca-carbonate or Ca-lactate (and not Ca-phosphate or bone meal) at 50 mg Ca/kg body weight might even accelerate osteoid mineralization. Corrective osteotomies can be planned, when necessary, after the skeleton is normally mineralized. Even pets with compression fractures of the spinal cord may have a full recovery.

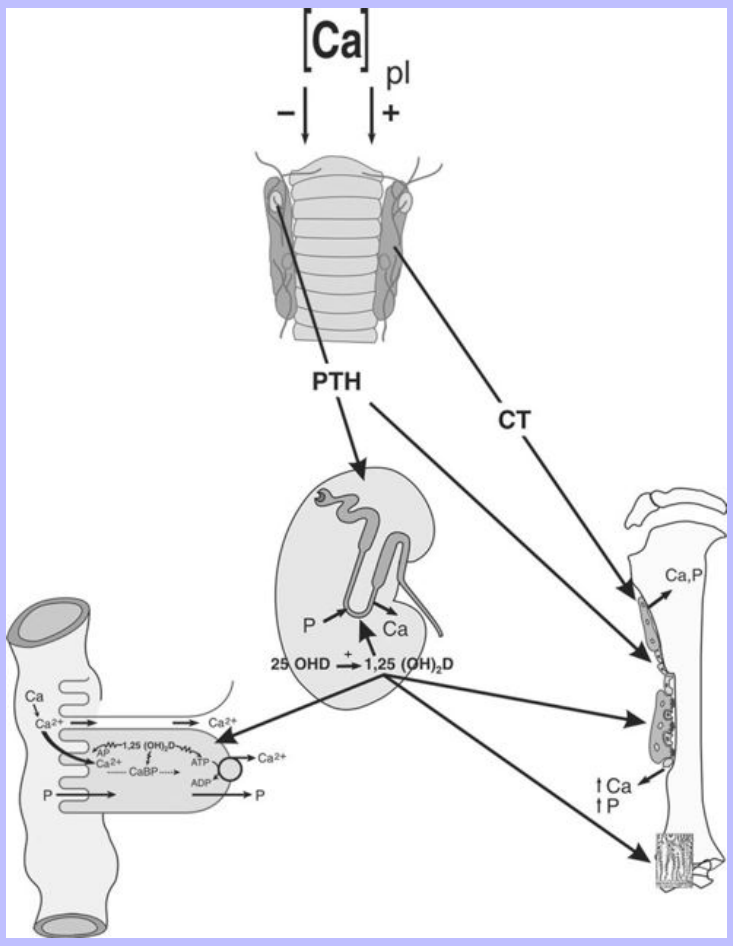
152.3 RICKETS

Hypovitaminosis D in young animals is known as *rickets*, whereas in adults it is called *osteomalacia*. Dietary vitD is absorbed by the intestine and transported to the liver where it is hydroxylated into 25-OHvitD.[1] Dogs and cats are not able to synthesize vitD in their skin under the influence of sunlight, unlike many other species.[1,4] A second hydroxylation takes place in the kidney, either to 24,25$(OH)_2$vitD or to 1,25$(OH)_2$vitD (calcitriol).[1] Calcitriol is the active metabolite that stimulates active absorption of Ca and P in intestine and renal tubular cells. Both metabolites are necessary for osteoid and cartilage mineralization.[1] Rickets is characterized by poor mineralization of newly formed osteoid and cartilage and a thickening of metaphyseal areas of bone.[4] Hypovitaminosis D in adult animals may be more common than the condition in young dogs and cats, but it does not cause obvious clinical signs. It might play a role in chronic renal insufficiency due to decreased capacity of hydroxylation of 25-OHvitD, despite renal secondary hyperparathyroidism. Normal vitD intake together with high Ca intake starting at an early age (3 weeks of life) may cause hypercalcemia, secondary hypoparathyroidism and tertiary decreased calcitriol formation. Rickets is the result.[5,6]

152.3.1 Clinical and Radiologic Examination

An unbalanced diet (either low in animal fat or enriched with calcium salts) fed from an early age onward is the most common problem. Thus a diet history is quite important.

Figure 152-1 Calcium homeostasis regulated by calciotropic hormones. An increase (+) of plasma calcium concentration $[Ca]_{pl}$ stimulates secretion of calcitonin (CT) from the thyroid glands with consequently retraction of the ruffle boarder of osteoclasts (OCL) with—in case of long duration—disturbance of skeletal remodeling and endochondral ossification. A decrease (–) of $[Ca]_{pl}$ stimulates parathyroid hormone (PTH) secretion from the parathyroid glands causing (1) shrinkage of osteoblasts, allowing OCL to resorb bone, and (2) increased reabsorption of Ca and excretion of P and increased formation of $1,25(OH)_2$vitD in the kidney. As a result of the latter, active absorption of Ca and P is increased, renal Ca and P reabsorption is increased, and mineralization of newly formed osteoid and cartilage is stimulated.



Radiographs demonstrate thin long bone cortices and extremely thickened growth plates. Plasma [Ca^{2+}] can be normal or low-normal due to hyperparathyroidism, also causing hypophoshatemia together with hyperphosphaturia (see Alimentary Hyperparathyroidism).[1,6] Determination of circulating vitD concentrations will reveal decreased levels of 25-OHvitD, whereas normal 25-OHvitD but low $1,25(OH)_2$vitD indicates alimentary induced hypoparathyroidism or renal disease.[1]

152.3.2 Treatment

First the diet has to be changed to a major commercial dog or cat food. These foods are known to contain sufficient vitD to resolve and prevent rickets.[1,4] Mineralization of bone cortices, callus, and growth plates will occur within 3 weeks. If the dog or cat fails to respond to a balanced diet, vitD therapy can be recommended.

152.4 HIP DYSPLASIA

Environment, including nutrition, plays a role in the expression of HD. Dogs raised on a diet with high Ca content instead of the recommended level of 1.1% Ca on dry-matter base, have retarded secondary ossification centers.[7] Delayed ossification of the skeleton at a given age, weight, and activity might allow for skeletal deformation when compared with dogs with a more advanced stage of skeletal development. In addition, excessive Ca intake will induce hypercalcitoninism, which may cause decreased skeletal modeling (see Figure 152-1). Changes in femoral neck angle during growth may result from osteoclast activity and can thus be hampered in animals with excess Ca intake.[8] Osteoclast activity can also be influenced by a change in base excess.[9] It has been suggested, but not proven, that an excess of cations (Na, K, Ca, Mg) and the expected compensatory alkalosis lowers bone cell activity and thus skeletal modeling.[9] Hypervitaminosis C can also cause hypercalcemia-induced hypercalcitoninism, contributing to the development of HD.[9,10] Excessive energy intake–induced excess in body weight has negative influences on hip joint development in dogs prone to HD.[9–11] Subluxation of the femoral head together with excess body weight causes the acetabular rim to deform as is seen in young dogs with severe HD. In addition, subluxation causes a corresponding increase in pressure on joint cartilage, which might cause irreversible cartilage damage and thus osteoarthrosis.[9] Excessive dietary protein per se has not proven to influence hip joint development.[3] High calorie intake may result in more rapid rate of growth of young dogs, both in length and in weight, and thus increase the risk of HD to develop.[9,12]

564

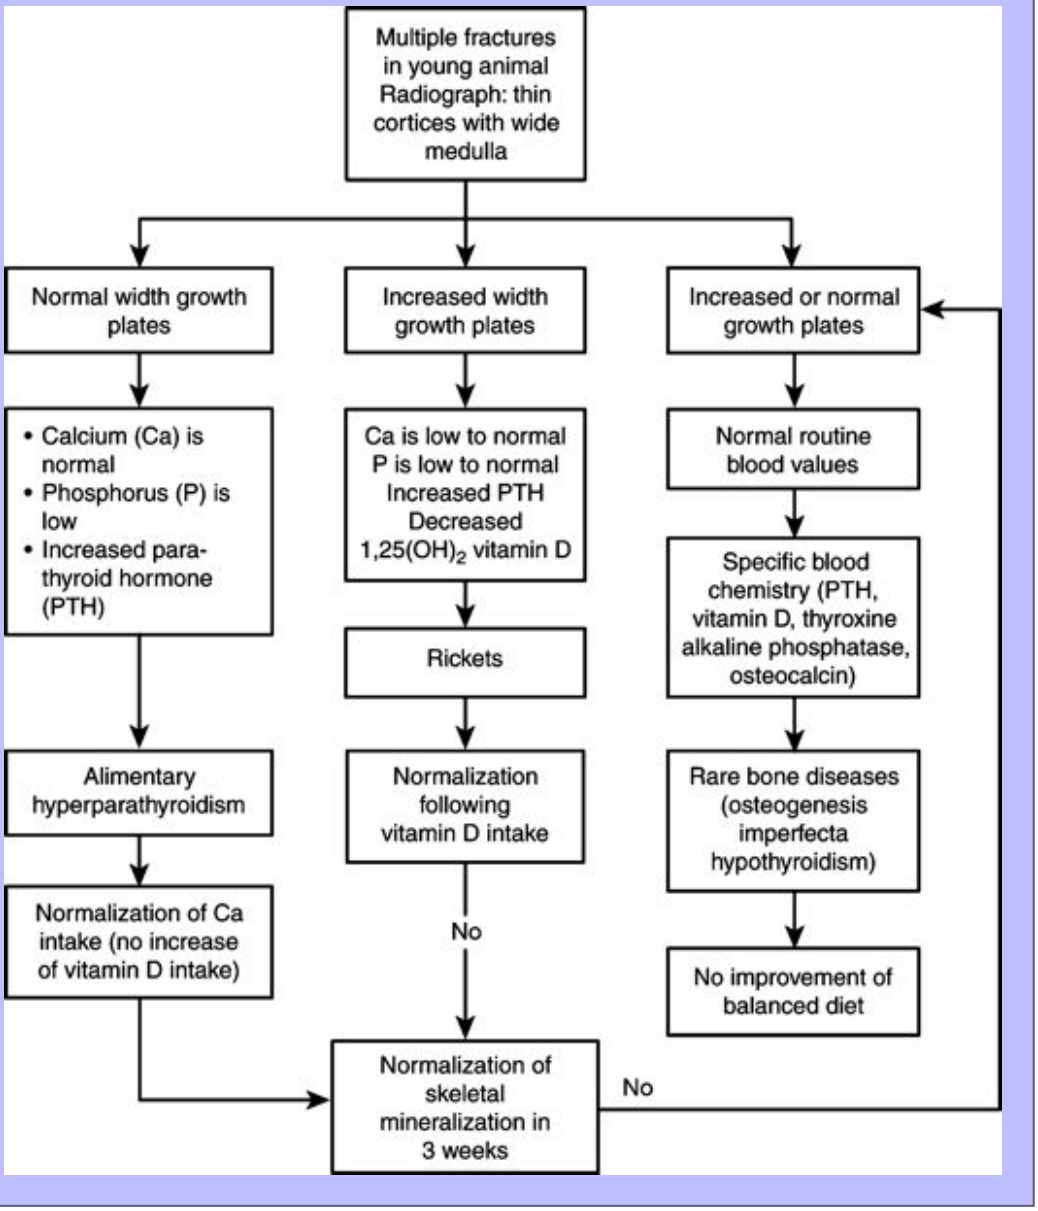
565

152.4.1 Treatment

Proper nutrition can help prevent HD. Proper nutrition in adult dogs can also serve as a conservative treatment of the osteoarthrosis due to HD. It is advocated to raise young dogs on a balanced diet with appropriate calories but without mineral excess. Nutritional treatment of osteoarthrosis should focus on weight reduction. Omega-3 fatty acids originating from fish may stimulate the synthesis of noninflammatory leukotrienes-5 (LTB_5) rather than the proinflammatory LTB_4. Combinations of chondroitin sulfate and glucosamine may be of benefit for treatment of osteoarthrosis when chronically administered at a dose of sufficient magnitude. In those cases where conservative treatment (activity reduction, appropriate diet and analgesics) is not sufficient in treating osteoarthrosis, surgery may be indicated. Diets restricted in calories (30% to 50% of the current quantity) might be used to assist in weight loss. However, these “light diets” should only be fed to overweight adult dogs and

not to growing young dogs, because the danger exists that such low-energy but complete dog foods fed to a young dog may cause excessive mineral uptake.[9,12]

Figure 152-2 An algorithm for multiple pathological fractures in young dogs and cats.



152.5 OSTEOCHONDROSIS

Growing cartilage is present in the growth plates and around the bony ends. Growth and closure of growth plates depends on age, breed, location, as well as on humoral and nutritional factors.[7] Overnutrition diets with excess Ca, diets with limited energy, and balanced foods with excessive vitD content[13] have all been proven to be important factors in the development of osteochondrosis (OC).[2–4,6,8,13] OC is a disturbance in the process of endochondral ossification of growth plates and joint cartilage. Ossification of cartilage will become clinically evident whenever fissure lines cause a cartilage flap (i.e., osteochondritis dissecans [OCD]). Not relative, but absolute amounts of mineral consumed per kilogram of body weight (or per kilogram of metabolic body weight) have to be taken into account.[6] Dietary Ca diffuses passively through the intestinal wall of the growing dog when dietary Ca content is larger than 1.0% on dry matter basis (dmb); therefore the absolute amount of ingested Ca determines the daily Ca absorption.[14] Ca excess causes hypercalcitoninism with decreased osteoclast activity, decreased skeletal remodeling, and (in large breed dogs) disturbed endochondral ossification.[2,3,8]

152.5.1 Clinical and Radiologic Examination

OC is considered to be a hereditary disease, seen most often in large breed males and rapidly growing females during their developmental growth phase. In case of retained cartilage cones, inspection of the front and rear legs may demonstrate bilateral valgus deformation.[4] In dogs with OCD, palpation and extension of shoulder, elbow, stifle, and tibiotarsal joints may demonstrate overfilling, pain reactions, or both. Measurement of circulating concentrations of Ca, P, calcitonin, and calcitriol may not provide insight into the dietary content or absorption rates of these elements.[5,6,13] Radiographs of growth plates or affected joints may reveal an abnormality in the alignment, whereas other imaging techniques, including arthroscopy, may support the diagnosis.[4,6]

565

566

152.5.2 Treatment

Young dogs of large breeds should be raised with limited amounts of food, preferably a food of good quality and containing ingredients according to the requirements of growing dogs.[9] Overfeeding and oversupplementation must be avoided. The increased level of protein in puppy food will not cause these skeletal disturbances![2,3] Surgery is indicated in case of malalignment or OCD.

152.6 PANOSTEITIS (= ENOSTOSIS = EOSINOPHILIC PANOSTEITIS)

Intake of food, and especially of Ca, causes the release of gastrointestinal (GI) hormones, some of which will cause calcitonin release from the thyroid glands. Increased plasma calcitonin concentrations prevent Ca release from the skeleton by influencing osteoclasts (see Figure 152-1). High Ca intake in young dogs leads to hyperplasia of calcitonin-producing cells with reduced osteoclastic activity, even months after an episode of high Ca intake.[2,6,8] In immature dogs, a large blood supply to the metaphyseal area (bordering the growth plates) exists. This network of arteriolae receives blood from branches of the periosteal side (i.e., the epiphyseometaphyseal arcade) and the medullary arteries. The latter enter the bone mainly in the foramen nutritium. The direction of efferent blood flow is through the diaphyseal cortex, centrifugal from medulla to periosteum, and runs through rigid bone canals including Volkmann's canals.[15] When, during growth, widening of the bony canals lags behind

the growing vessels, vessel occlusion will result in edema formation inside the medullary cavity. Ultimately, new bone formation will take place on the fibrous tissue formed. Increased pressure and finally new bone formation is first seen near the foramen nutritium. Edema may also accumulate underneath the periosteum and thus make the periosteum painful in response to pressure or muscle activity, causing extra lamellar bone formation.[5] So far, no causes other than high food[8] and Ca[6] intake have been demonstrated.

152.6.1 Clinical and Radiologic Investigation

Panosteitis is mainly seen in medium and large-breed dogs (especially German shepherd dogs), starting at 6 months of age with a sudden onset of shifting lameness showing pain reaction upon deep palpation at several long bones. An increased body temperature may be present. Blood investigation or culture of blood or bone is negative, although electrophoresis of plasma proteins may reveal abnormalities.[16] Radiographs demonstrate a blurring of the trabecular pattern and well-defined subperiosteal cortical thickening can be noticed.

152.6.2 Therapy

Because the disease is self-limiting and is not diagnosed in dogs over 22 months of age, treatment is limited to analgesics and nursing of the dogs. Analgesics can relieve pain. Dietary corrections include a decrease in the amount of Ca to the minimal requirements for dogs. The role of dietary proteins is suggested by some[16] and rebutted by others.[2,3]

153 CHAPTER • 153 Adverse Reactions to Foods: Allergies versus Intolerance

Philip Roudebush

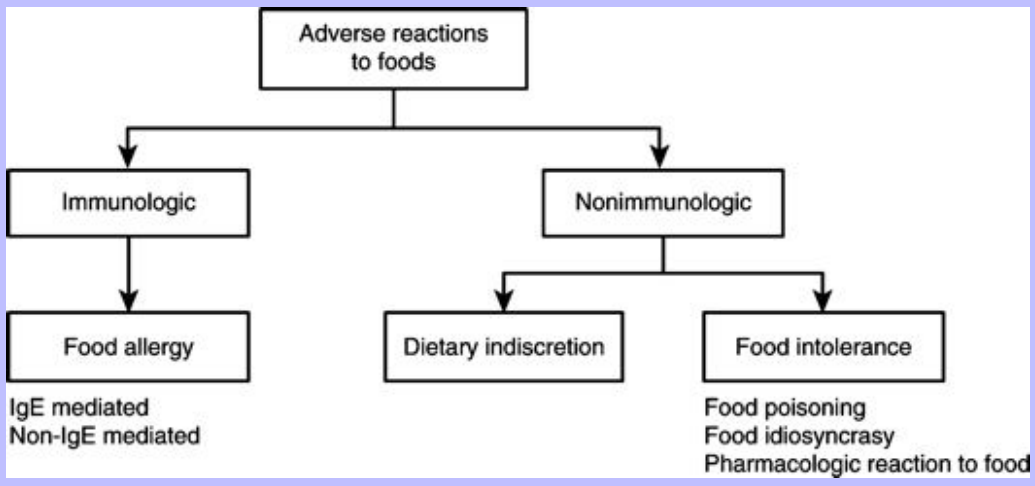
An adverse reaction to food is a clinically abnormal response to an ingested food or food additive. In general, the pathogenic mechanisms that cause adverse food reactions include ingestion of the inciting agent followed by interaction of the agent with a biologic amplification system that leads to inflammation and clinical signs.

In view of the number of diverse foods that are routinely ingested by animals, it is not surprising that adverse reactions develop to dietary substances. The fact that food-related reactions appear relatively infrequently is testimony to the effectiveness of the intestinal mucosal barrier and oral tolerance. Adverse reactions to food have been blamed for a variety of clinical syndromes in cats and dogs, usually involving the skin and gastrointestinal tract.

153.1 TERMINOLOGY

Adverse reactions to food comprise a variety of subclassifications based on pathomechanisms. The following terms and definitions are recommended by the American Academy of Allergy and Immunology (Figure 153-1).[1,2] *Food allergy (food hypersensitivity)* is an adverse reaction to a food or food additive with a proven immunologic basis. *Food anaphylaxis* is an acute food allergy with systemic consequences, such as respiratory distress, vascular collapse, and urticaria. *Food intolerance* is a nonimmunologic, abnormal physiologic response to a food or food additive. Food intolerance can be further classified as food idiosyncrasy, food poisoning, and pharmacologic reactions to food. *Food idiosyncrasy* is an abnormal response that resembles food allergy but that does not involve immune mechanisms. A direct nonimmunologic action on the host of food or a toxin in food is termed *food poisoning*. Adverse reactions due to a druglike or pharmacologic effect of a food substance on the host are called *pharmacologic reactions to food*. When adverse reactions result from such behaviors as gluttony, pica, or ingestion of indigestible materials, the term *dietary indiscretion* is used. Traditionally, the term *food allergy* has been used to describe all adverse reactions to food in dogs and cats, including reactions that were actually food intolerance.

Figure 153-1 Classification of adverse reactions to food.



153.2 FOOD ALLERGENS

The specific food allergens that cause problems in animals have been poorly documented. In general, the major food allergens that have been identified in human beings are water-soluble glycoproteins that have molecular weights ranging from 10,000 to 70,000 daltons and that are stable when treated with heat, acid, or proteases.[3,4] Other physiochemical properties that account for their unique allergenicity are poorly understood.

Twelve different studies, representing a total of 265 dogs, have described cutaneous lesions associated with adverse reactions to specific foods or ingredients.[5] These studies reported findings from a wide geographic area, including the United States, United Kingdom, France, Australia, and Japan. Adverse reactions to beef, dairy products, and wheat accounted for two thirds of reported cases in dogs. Adverse reactions to chicken, chicken eggs, lamb, or soy accounted for approximately 25% of reported canine cases. Adverse reactions to corn, pork, rice, or fish ingredients are rarely reported in dogs.

In cats, 10 different studies, representing a total of 56 animals, have described cutaneous lesions or gastroenteric signs associated with adverse reactions to specific foods or ingredients.[5] These studies have also reported findings from a wide geographic area, including the United States, United Kingdom, France, New Zealand, and Japan. Adverse reactions to beef, dairy products, and fish accounted for more than 80% of reported cases.

Human allergy reference books often have phylogenetic tables of animal and vegetable foods so that food-allergic individuals can avoid other closely related foods. Cross-reactivity among food allergens has been only briefly investigated in pet animals.[6]

153.3 FOOD INTOLERANCE

Nonimmunologic, abnormal physiologic reactions to food include food intolerance and dietary indiscretion (see Figure 153-1). Like the term *food allergy,* the term *food intolerance* has been applied inappropriately to any and all adverse reactions to food. Food intolerance mimics food allergy except that it can occur with the first exposure to a food or food additive, because nonimmunologic mechanisms are involved. The incidence of food intolerance versus food allergy in animals is unknown.

Idiosyncratic adverse reactions to food additives often occur in human beings. Although food additives are frequently cited as the cause of problems in dogs and cats, few data confirm this perception. Propylene glycol and onion ingredients have been documented to cause hematologic abnormalities in cats.[7,8]

Another cause of food intolerance is pharmacologic reactions to substances found in food. Vasoactive or biogenic amines such as histamine cause clinical signs when present in excessive levels in food. Adverse reactions to histamine in scombroid fish (e.g., mackerel, tuna) have been observed in cats and dogs.[9] Vasoactive or biogenic amines may not be present in levels high enough to cause clinical signs, but they may lower the threshold levels for allergens in individual dogs and cats.

The diarrhea, bloating, and abdominal discomfort that occur when animals with lactose intolerance ingest milk are relatively common metabolic adverse reactions in dogs and cats. Osmotic diarrhea often occurs when excessive levels of lactose are consumed. Puppies, kittens, or adult animals may develop diarrhea when given cow's or goat's milk because these milk sources contain more lactose than either bitch's or queen's milk.

Intolerance to disaccharides commonly occurs secondary to enteritis or rapid food changes. Loss of intestinal brush border disaccharidase activity contributes to the diarrhea associated with enteritis. Inadequate intestinal disaccharidase activity is another factor responsible for diarrhea subsequent to rapid food changes. Several days are required for intestinal disaccharidase enzyme activity to adapt to changes in food carbohydrate sources.

153.4 CLINICAL FEATURES IN DOGS AND CATS

153.4.1 Dermatologic Responses in Dogs

Reports of adverse food reactions in dogs with cutaneous disease did not document a gender predisposition, and ages ranged from 4 months to 14 years. However, up to one third of canine cases may occur in dogs less than 1 year old. Because many adverse food reactions occur in young dogs, the index of suspicion for food allergy may rise above that for atopic dermatitis when intense pruritus occurs in dogs less than 6 months old. Most investigators have not found a breed predilection, whereas others have found that cocker spaniels, springer spaniels, Labrador retrievers, collies, miniature schnauzers, Chinese Shar Pei, West Highland white terriers, wheaten terriers, boxers, dachshunds, Dalmatians, Lhasa apsos, German shepherds, and golden retrievers are at increased risk.

567
568

Adverse food reactions in dogs typically occur as nonseasonal pruritic dermatitis, occasionally accompanied by gastrointestinal (GI) signs. The pruritus varies in severity. Lesion distribution is often indistinguishable from that seen with atopic dermatitis; the feet, face, axillae, perineal region, inguinal region, rump, and ears are often affected. Many dogs with adverse food reactions have lesions only in the region of the ears. This finding suggests that adverse food reactions should always be suspected in dogs with pruritic, bilateral otitis externa, even if it is accompanied by secondary bacterial or yeast infections.

Adverse food reactions often mimic other common canine skin disorders, including pyoderma, pruritic seborrheic dermatoses, folliculitis, and ectoparasitism. Twenty percent to 30% or more of dogs with suspected adverse food reactions may have concurrent allergic disease, such as flea-allergy or atopic dermatitis.

Food anaphylaxis is an acute reaction to food or food additives with systemic consequences. The most common clinical manifestation in dogs occurs in localized form and is referred to as *angioedema* or *facioconjunctival edema*. Angioedema is typically manifested by large, edematous swellings of the lips, face, eyelids, ears, conjunctivae, and/or tongue, with or without pruritus. Most veterinary practitioners attribute angioedema solely to insect envenomation (biting or stinging insects); however, a number of other common causes are food, drugs, vaccines, infections, atopy, and blood transfusions. Urticarial reactions (hives) are characterized by localized or generalized wheals, which may or may not be pruritic. They usually occur within minutes of allergen exposure and generally subside after 1 to 2 hours.

153.4.2 Dermatologic Responses in Cats

Gender predisposition has not been documented in adverse food reactions in cats, and ages have ranged from 6 months to 12 years. Siamese and Siamese-cross cats may be at increased risk, because they have accounted for nearly one third of cases.

Dermatologic signs include several different clinical reaction patterns, such as (1) severe, generalized pruritus without lesions; (2) miliary dermatitis; (3) pruritus with self-trauma centered around the head, neck, and ears; (4) traumatic alopecia; (5) moist dermatitis; and (6) scaling dermatoses. Angioedema, urticaria, and

conjunctivitis occur commonly in cats with adverse food reactions. Adverse reactions to food may also cause self-inflicted alopecia (psychogenic alopecia, or neurodermatitis), eosinophilic plaques, and indolent ulcers of the lips in some cats. Concurrent flea-allergy or atopic dermatitis may occur in up to one third of cats with suspected adverse food reactions.

Moderate to marked peripheral lymphadomegaly and absolute eosinophilia are commonly found in cats with dermatologic manifestations of food allergy.

153.4.3 Gastrointestinal Responses in Dogs and Cats

Gender predilections have not been established for GI disease resulting from adverse reactions to foods. Similarly, there are no well-documented breed predispositions to GI food allergy, but Chinese Shar Peis and German shepherds are commonly affected. Gluten-sensitive enteropathy has been well documented in Irish setters. A wide age range of patients can be affected, including dogs and cats as young as weaning age.

Every level of the GI tract can be damaged by food allergies. In cats and dogs, clinical signs usually relate to gastric and small bowel dysfunction, but colitis can also occur. Vomiting and diarrhea are prominent features. The diarrhea can be profuse and watery, mucoid or hemorrhagic. Intermittent abdominal pain is occasionally observed. Concurrent cutaneous signs may be seen. GI disturbances occur in up to 50% of dogs and cats with cutaneous manifestations of food sensitivity. These GI disturbances may be relatively mild such as soft feces, intermittent diarrhea, flatus, and increased frequency of defecation. Adverse reactions to food should always be considered likely in dogs and cats with concurrent cutaneous and GI signs.

The role of food allergy in canine and feline inflammatory bowel disease is unknown. Hypersensitivity to food is probably involved in the pathogenesis of this syndrome; at least some affected animals could be more appropriately diagnosed as suffering from food protein-induced enterocolitis.[2]

Irritable bowel syndrome is a disease of dogs characterized by chronic recurrent abdominal pain and large bowel diarrhea. Feeding changes often alleviate the signs of irritable bowel disease, implying that food allergy or food intolerance plays a role in this syndrome.

153.5 DIAGNOSIS

Dietary elimination trials are the main diagnostic method used in dogs and cats with suspected adverse food reactions. At the present time, intradermal skin testing, radioallergosorbent tests (RASTs), and enzyme-linked immunosorbent assays (ELISAs) for food allergy are considered unreliable in animals.[10,11]

The ideal elimination food should (1) include a protein hydrolysate or reduced number of novel, highly digestible protein sources; (2) avoid protein excesses; (3) avoid additives and vasoactive amines; and (4) be nutritionally adequate for the animal's life stage and condition.[12] Excess protein levels should be avoided so as to reduce the amount of potential allergens to which the dermatologic patient is exposed. However, a higher protein level may be necessary to counteract protein losses from the GI tract or impaired absorption in patients with hypoproteinemia and weight loss associated with severe GI disease. Although elimination trials are performed only for several weeks to months, the food used in the trial should be nutritionally complete and balanced for the intended species, age and lifestyle of the animal. Elimination trials are often performed with young animals, in which nutritionally inadequate foods are more likely to result in nutritional disease.

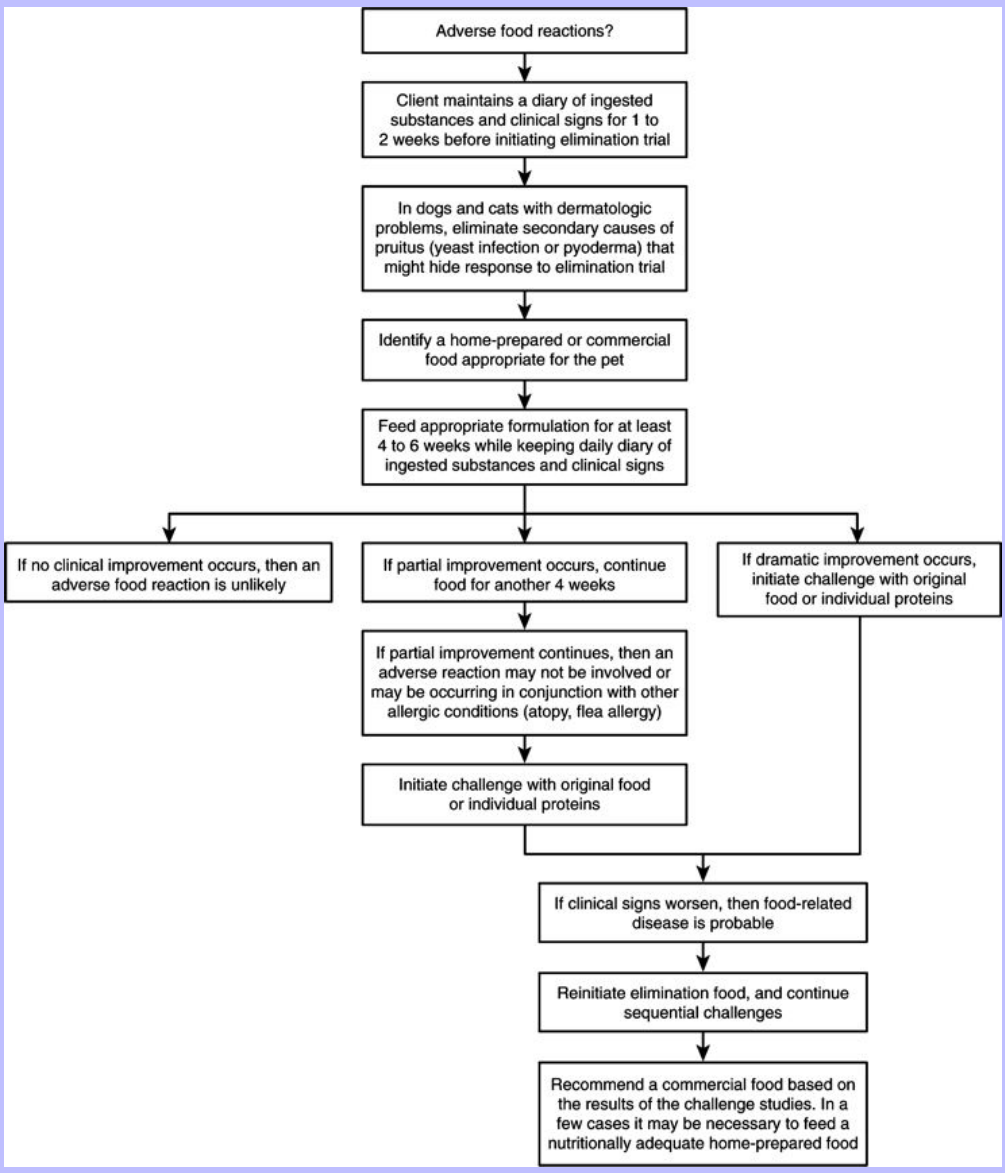
153.5.1 Homemade Elimination Foods

Homemade foods are often recommended as the initial test food for dogs and cats with suspected food allergy. Homemade test foods usually include a single protein source or a combination of a single protein source and a single carbohydrate source. However, many homemade foods fail to meet nutritional requirements because they are made from a minimum of ingredients.[12] In general, homemade foods lack a source of calcium, essential fatty acids, certain vitamins, and other micronutrients and contain excessive levels of protein, which are contraindicated in animals with food allergy. Feeding nutritionally inadequate homemade foods for more than 3 weeks may result in nutritional disease, especially in young animals.

153.5.2 Commercial Elimination Foods

A variety of foods with limited and different protein sources are manufactured by several companies. These commercial products are attractive because they are convenient and nutritionally complete and balanced for either cats or dogs. The newest concept for managing animals with suspected adverse food reactions is use of commercial foods containing hydrolyzed protein ingredients. Veterinary therapeutic foods containing protein hydrolysates offer several hypothetical advantages over traditional commercial or homemade elimination foods. Protein hydrolysates of appropriate molecular weight (less than 10,000 daltons) do not elicit an immunologically mediated response and may be regarded as truly “hypoallergenic” ingredients. Novel or unique protein sources are less important with protein hydrolysates. Protein hydrolysates have been used for many years in human infant formulas and for human patients with various gastrointestinal diseases.

Figure 153-2 Protocol for elimination-challenge trials for the diagnosis of adverse reactions to food. (From Hand MS, Thatcher CD, Remillard RL, et al [eds]: Small Animal Clinical Nutrition, 4th ed. Topeka, Kansas, Mark Morris Institute, 2000.)



Few commercial foods have been adequately tested in dogs and cats with known adverse food reactions; only a few commercial foods have undergone the scrutiny of clinical trials using patients with dermatologic or GI disease. In published clinical trials, two thirds to three fourths of patients with suspected adverse food reactions showed significant improvement in clinical signs when fed commercial foods.

569

570

153.5.3 Performing an Elimination Trial in Patients with Dermatologic Disease

Before an elimination trial is initiated, the client should feed the animal its usual food for several days. During this time, the client should record the type and amount of food ingested, any other ingested food items (e.g., table scraps, treats, and snacks), and the occurrence and character of adverse reactions. The patient is then fed a controlled elimination food for 4 to 12 weeks. During the elimination trial, no other substances should be ingested, including treats, flavored vitamin supplements, chewable medications, fatty acid supplements, or chew toys. The client should document daily the type and amount of food ingested and the occurrence and character of adverse reactions. A daily food diary helps document progression of clinical signs during the elimination trial and whether a strict elimination trial was performed in the home environment. Examples of food diaries can be found in other publications.[12]

A tentative diagnosis of an adverse food reaction in dermatologic patients is made if the level of pruritus markedly decreases. This improvement may be gradual and may take 4 to 12 weeks to become evident.

A diagnosis of an adverse food reaction is confirmed if clinical signs reappear 10 to 14 days after the animal's former food and other ingested substances are offered as a challenge.

Elimination trials are often difficult to interpret because of concurrent allergic skin disease. Patients with other allergic diseases may only partially respond to an elimination trial. Flea-allergy and atopic dermatitis are the most common canine and feline allergies and should be eliminated through other diagnostic testing.

153.5.4 Performing an Elimination Trial in Patients with Gastrointestinal Disease

Elimination-challenge trial designs for patients with GI food disease are similar to those for patients with dermatologic problems (Figure 153-2). However, shorter elimination periods (2 to 4 weeks) are usually satisfactory. In chronic relapsing conditions, the elimination period chosen must be greater than the usual symptom-free period of the patient to allow reliable assessment of how food sensitivity contributes to the patient's signs.

As with skin disease, the degree of clinical improvement during the elimination trial will be 100% only if food allergy or food intolerance is the sole cause of the patient's problems. For instance, resolution of allergies acquired as a result of GI disease will not eliminate the clinical signs due to the primary GI disease process. Recrudescence of GI signs after challenge of a food-sensitive patient with the responsible allergen usually occurs within the first 3 days but may take as long as 7 days, particularly if the responsible allergen was removed from the food for longer than 1 month.

153.6 TREATMENT

For most food allergies, avoiding the offending foods is the most effective treatment. How selective or meticulous an avoidance diet must be depends on the individual animal's sensitivity. Some dogs and cats may suffer adverse reactions to even trace amounts of an offending food, whereas others may have a higher tolerance level. Concurrent allergies influence the threshold level of clinical signs in some animals. Symptomatic therapy in pruritic animals can also include corticosteroids and antihistamines. Corticosteroids, along with dietary change, are often used in cats with inflammatory bowel disease.

Both homemade and commercial foods can be used for long-term maintenance of patients with suspected food allergy. It is very important that any homemade recipe for long-term maintenance ensures a nutritionally adequate ration. An attempt should always be made to find an acceptable commercial food that will increase owner compliance with the dietary change and ensure a nutritionally adequate ration.

154 CHAPTER • 154 Nutritional Management of Gastrointestinal Conditions

Debra L. Zoran

The gastrointestinal (GI) tract is a complex systemprimarily responsible for acquiring and digesting food, absorbing nutrients and water, and expelling wastes from the body in the form of feces. A proper diet andnormally functioning GI tract are integral to the deliveryof nutrients, the prevention of nutrient deficiencies andmalnutrition, the repair of damaged intestinal epithelium, the restoration of normal luminal bacterial populations, the promotion of normal GI motility, and the maintenanceof normal immune functions (e.g., both tolerance of andprotection from pathogens).[1] Dietary characteristics, suchas the amount of food, its form, the frequency of feeding, and the composition of the diet, also have important effects on GI function and may be used to help ameliorate signsof disease. Both nutrients and non-nutritional componentsof a diet support normal GI functions, but they also maycause or influence the development of GI pathology (e.g., antibiotic-responsive diarrhea [ARD], inflammatory bowel disease [IBD], and dietary intolerance or sensitivity/allergy). In chronic or severe GI disturbances, diet may have a profound effect on intestinal recovery and successful management of the disease.

154.1 ROLE OF CONSISTENCY, FREQUENCY, AND MEAL SIZE

For many acute, non-life-threatening GI disturbances, treatment customarily includes the withholding of food and water for24 to 72 hours, along with correction of fluid and electrolyte deficits. This approach often is an effective treatment forvomiting or diarrhea due to dietary indiscretion or for mild forms of infectious or toxin-induced gastroenteritis.[2] After this short fasting period, the dog or cat should be fed a highly digestible diet (i.e., minimal fat and easily digested proteinand carbohydrate [CHO] sources). This should be followed by gradual reintroduction of the original diet. In previously healthy animals, fasting would not be expected to be harmful nutritionally, systemically, or to the GI tract. However, the traditional approach of “resting” the GI tract (i.e., extended fasting) may be harmful or may prolong recovery, especially in injured or sick animals fasted longer than 3 to 4 days or in any nutritionally compromised animal. Deficiency of protein and calories leads to immune system dysfunction, reduced availability of antioxidants and free radical scavengers, reduced energy for vital cellular functions, lack of precursors for repair of injured or diseased tissue and, ultimately, loss of lean body mass.[3] Prolonged fasting also deprives the GI epithelium of its primary metabolic fuel source, the glutamine present in chyme.[4] This metabolic fuel is necessary not only for replacement of theGI mucosal cells lost in normal turnover (every 3 to 5 days), but also for repair of mucosal injury.[4]

One alternative is to provide an oral rehydration solution containing CHO, peptides, and electrolytes to “feed through the diarrhea” in animals that are not vomiting or severely dehydrated (including glutamine).[5] However, if the animal is vomiting or the gut is not functional, the animal's protein (including glutamine) and calorie needs, can and should be met through parenteral nutritional support.[6] Whatever route is chosen, feeding should be instituted as soon as possible. A good rule of thumb for induction of nutritional support is the 3-5-7 day rule: On day 3 of anorexia, planning should begin for implementation of nutritional support, and the plan should be implemented by day 5; otherwise, by day 7 protein and calorie malnutrition will occur, requiring an immediate response.

A major consideration in choosing a diet to feed an animal with GI disease is nutrient digestibility. Typical maintenance pet foods have protein and CHO digestibilities ranging from 70% to 85% on a dry matter (DM) basis.[7] Pet foods formulated for dietary therapy of GI disease have CHO and protein digestibilities of 90% DM or

higher.[7] Therapeutic dietsalso have low levels of fat (less than 15% DM in cats and less than 10% to 15% DM in dogs), are lactose free, and have reduced amounts of dietary fiber and other poorly digestible CHO. Many different, highly digestible, therapeutic diets areavailable. Each formula is unique and therefore can elicit adifferent individual response. For example, these diets have different protein or CHO sources and varying levels and types of fat (e.g., some add omega 3 fatty acids), and some areformulated with ingredients designed to enhance GI health, such as fructooligosaccharides (FOS). Although the benefits of these individual additives have not been proven in large clinical trials, feeding highly digestible diets to pets with both acute and chronic GI diseases is widely accepted as beneficial.

The amount of a diet fed should be calculated based onthe energy needs of the individual animal. Although there is ongoing discussion among nutritionists regarding the best equation for determining the energy requirements of sick animals, at the very least, the resting (or basal) energy requirements (RER) should be met.[8] One generally accepted equation for determining resting energy requirements in dogs and cats is 70 $(BW_{kg})^{0.75}$. Once energy requirements have been determined, meal size, frequency, and consistency are considered. Generally, small meals (e.g., less than one third of stomach capacity) are fed several times per day (three to six meals). The feline stomach has a smaller capacity (approximately 60 mL/kg) and is less distensible than the stomach of a dog (nearly 80 to 90 mL/kg), which is designed for greater storage.[9] Feeding small meals reduces gastric distension, decreases gastric acid secretion, and may reduce nausea, vomiting, and gastroesophageal reflux.[1,7] Furthermore, the larger the volume of food ingested, the less that can be effectively assimilated. In general, liquid diets empty faster from the stomach than canned foods, and canned foods empty faster than dry.[7] Therefore if liquid diets are fed too quickly or in large volumes, diarrhea may occur. In veterinary medicine, liquid diets are primarily used in specialized circumstances (e.g., for nasoesophageal or jejunostomy tube feeding) or with certain GI conditions (e.g., esophageal stricture, selected cases of megaesophagus, or gastric outflow disturbances) because they may reduce regurgitation or vomiting.

154.2 NUTRIENT COMPOSITION

A variety of nutritional and non-nutritional diseases affect the GI tract; however, treatment of most GI disease is enhanced by appropriate diet selection. Numerous therapeutic diets are available for treatment of GI disease, including highly digestible diets, novel antigen or so-called hypoallergenic diets, hydrolyzed protein diets, and diets with increased dietary fiber. Each of these diets may be used in the management of various GI disturbances; however, selection of the most appropriate diet requires an understanding of the differences in the nutrient composition of these formulations. Furthermore, under some circumstances, specific diets (e.g., homemade or novel) are required for successful dietary management of severe GI disease.

154.3 PROTEIN

The effects of protein on the GI tract are subtle and oftenless clinically obvious than those of fat or CHO, but they are no less important. Protein in the GI tract increases lower esophageal sphincter pressure; is a potent stimulus for the secretion of hormones, including gastrin and pancreatichormones; and increases both gastric emptying and intestinal transit.[1,7] Despite this, protein malassimilation is not a major stimulus for diarrhea; for example, dogs with protein-losing enteropathies (PLE) often do not have diarrhea unless they have concurrent fat malabsorption. However, intact protein reaching the distal small intestine and colon increases bacterial ammonia production, alters bacterial numbers and species, and may contribute to colitis or colonic hypersensitivity.[10] Furthermore, protein antigens in food are responsible for the development of most food hypersensitivity reactions in dogs and cats (see Chapter on food hypersensitivity). In animals with severe mucosal disruption (e.g., IBD, lymphoma),

intact proteins cross the mucosa, exposing the mucosal immune cells of the lamina propria to these antigens. This results in the development of hypersensitivity to that protein and perpetuation of the aberrant immune response. For this reason, feeding a “sacrificial” diet during the initial stages of therapy of severe GI disease, until the inflammation is under control, has been recommended.[11] Once the inflammatory disease has been suppressed, a new, highly digestible or novel antigen diet can be introduced for long-term therapy. Feeding hydrolyzed diets (e.g., peptides of less than 15,000 daltons) in this situation may be beneficial as there is no intact protein to stimulate animal response. However, epitopes may still exist on these peptides that can be recognized as foreign, and thus may not eliminate the possibility of immune stimulation, nonetheless, anecdotal evidence suggests many dogs and cats benefit from this dietary approach.

571

572

Protein-losing enteropathies are a group of severe intestinal diseases that occur as primary enteropathies (e.g., lymphangiectasia) or familial enteropathies (e.g., soft-coated wheaten terriers, basenjis, Irish setters[12]). Alternatively, they occur secondary to infectious, neoplastic, or inflammatorydiseases that infiltrate the GI mucosa and result in loss of mucosal function, including malassimilation of nutrients, motility disturbances, and loss of normal gut functions.[12] Protein loss may also occur from a lack of available or functional enzymes, such as exocrine pancreatic insufficiency (EPI). Regardless of the cause, nutritional therapy is anessential aspect of successful management of PLE. Inmild forms of PLE, feeding a highly digestible, low-fat diet, in addition to specific therapy for the primary disease, maybe sufficient. However, when severe intestinal disease results in significant loss of serum proteins (serum albumin lessthan 1.5 g/dL), subsequent development GI mucosal edema causes further nutrient malassimilation. In these animals, hydrolyzed diets or elemental diets (e.g., diets containing no intact nutrient sources) may be required. In animals with severe PLE, a combination of parenteral and enteral nutrition may also be needed to replace lost oncotic proteins, resolvegut edema, and correct protein-calorie malnutrition. Once serum albumin concentrations are more stable (greater than 1.75 g/dL) highly digestible, low-fat diets containing intact protein may be tolerated. However, some dogs with PLE may require feeding of ultra-low-fat homemade diets (e.g., nonfat cottage cheese, egg whites, rice, cooked potatoes) or combinations of hydrolyzed, ultra-low-fat (less than 10% fat DM), or elemental diets indefinitely.[11]

154.4 FATS AND FATTY ACIDS

Generally, the higher the density of nutrients, the slower the food empties from the stomach. This is primarily because most nutrient-dense foods are higher in fat, which slowsgastric emptying in both dogs and humans but not in cats.[1,7] In contrast to the effects of protein, increased levels of dietary fat decrease the tone of the lower esophageal sphincterand may lead to an increased risk of gastroesophageal refluxor vomiting.[13] Because digestion and absorption of fat isa complex process, malassimilation of fat in animals withGI disease is common. Fat or fatty acids reaching the distal ileum or colon increase the fermentation of bacteria (especially nonbeneficial species), result in the formation of proinflammatory and prosecretory hydroxy fatty acids, andcan cause osmotic diarrhea.[10,13] Nevertheless, the complete absence of fat from the diet is also undesirable and maylead to a deficiency of essential fatty acids. Essential fattyacids must be supplied to provide the phospholipid and cholesterol building blocks for cellular growth and repair and for synthesis of prostaglandins, leukotrienes, and thromboxanes.[13] Dietary fat is also important because it enhances the palatability and acceptance of food, and it is an essential energy source for sick or injured animals that cannot effectively utilize CHO.

Recently, attention has been focussed on the addition of anti-inflammatory omega 3 fatty acids (fish oils) to dietsused for therapy of GI disease. In humans with ulcerativecolitis, the addition of fish oils to the diet resulted in a reduction in inflammatory mediators, improved mucosal function and fluidity, and reduced the use of anti-inflammatorydrugs to maintain control of the disease.[14] The clinical benefit of fish oils in the treatment of

inflammatory skin disease in dogs is well recognized; however, studies specifically assessinga reduction of intestinal inflammation in dogs and catsfed omega 3 fatty acids are lacking. Nevertheless, sometherapeutic diets have omega 3 fatty acids added to theirformulations.

154.5 CARBOHYDRATES

There are no requirements for CHO in the diet of dogs or cats. The CHO present in pet foods are primarily plant starches, such as rice, potato, corn, wheat, and barley.[13] Another typeof CHO present in some diets are the beta-linked polysaccharides (i.e., those not readily broken down by mammalian amylases), which include the dietary fibers.[13] CHO digestibility is determined by its origin and the degree of cooking;for example, rice and wheat are generally highly digestible, whereas uncooked maize or potato starch is less digestible.[13] CHO malassimilation results in the development of osmotic diarrhea, the production of increased intestinal gas (flatus), loss of water and electrolytes, increased fermentation ofbacteria in both the small intestine and the colon, overgrowth of pathogenic bacteria, and acidification of the colonic luminal environment, promoting the formation of hydroxy fatty acids and other potentially toxic intermediates.[7,13] White rice is the CHO of choice for most dogs (and is the most commonly used CHO in therapeutic diets), because it is gluten free (some dogs, especially Irish setters and soft-coated wheaten terriers, are sensitive to gluten or may develop sensitivity to gluten, which is present in wheat, oats, and barley), highly digestible, and nonantigenic.[1,2,7,12] Other gluten-free CHO sources include potato, corn, and tapioca, but potato and tapioca are less digestible, and corn may be antigenic to animals prone to develop food sensitivity.

Dietary fibers are a large, complex group of CHO that include starch and nonstarch polysaccharides found in plants; they are readily digested by bacterial enzymes but less well digested by mammalian enyzmes.[13] Traditionally, fibers were classified as *soluble* (highly fermentable) or *insoluble* (poorly fermented or nonfermentable) based on their digestion by amylase; however, a physiologically relevant classification, based on their activity in the GI tract, is currently recommended. Fibers are soluble if they form gels in solution (thus attracting water), delay gastric emptying and slow intestinal transit, inhibit the absorption of cholesterol and some other nutrients, are poor bulking agents, are highly fermentablein the colon (i.e., increase the numbers of bacteria and increase short chain fatty acids, especially butyrate, an essential colonic fuel source), acidify the lumen, and stimulate colonic cellular proliferation.[1,15] Examples of soluble fibers include FOS, pectins, psyllium, oats, barley, guar gum, fruits, and some legumes.[13] Insoluble fibers do not form gels, haveno effect on gastric emptying, increase or “normalize” intestinal transit, have no effect on nutrient absorption, are good bulking agents (i.e., dilute colonic content and thus bindnoxious agents in the colon), are fermented less and therefore produce fewer short chain fatty acids, and increase fecal weight.[1,15] Typical examples of insoluble fibers are cellulose, wheat and rye fibers (most cereal fibers), and the woody parts of plants (e.g., lignins).[13]

FOS are kestose or nystose sugars present in a varietyof fruits, vegetables, and grains that behave in the GI tractlike soluble fibers. These sugars have generated considerable interest in both human and veterinary medicine, because they are preferentially fermented by beneficial bacterial species(e.g., *Lactobacillus* and *Bifidobacteria* spp.) and prevent the growth of pathogenic species.[16] In studies of humans with IBD or colitis, adding FOS to the diet greatly improved the response to therapy, clinical disease was reduced, and relapses were fewer.[17] Only a few studies in dogs (and even fewer in cats) have evaluated the role of FOS in the dietary therapy of GIdisease. However, preliminary evidence supports the finding in humans that FOS increases the numbers of beneficial bacteria in the colon of both dogs and cats[18,19] and may prove beneficial in controlling bacterial overgrowth, ARD, or other inflammatory diseases believed to have a bacterial origin (e.g., IBD).

572 573

Table • 154-1 Vitamin Deficiencies Caused by Severe Intestinal Disease

VITAMIN	SIGNS OF DEFICIENCY	COMMENTS
A	Impaired growth, loss of epithelial integrity	Stored in liver; deficiency is rare
D	Osteomalacia, nutritional secondary hyperparathyroidism	Stored in liver; cats more likely to be deficient
E	Dermatoses, pansteatitis	Caused by malabsorption
K	Hemorrhage, increased PT	Caused by fat malabsorption
Thiamin (B_1)	CNS dysfunction, anorexia, muscle weakness	Cats more likely to be deficient; thiaminase
Riboflavin (B_2)	CNS dysfunction, dermatitis	Important cofactor in energy metabolism
Niacin (B_3)	Oral/mucosal disease	Cannot be synthesized by cats, which have a greater requirement for B_3
Pyridoxine (B_6)	Microcytic, hypochromic anemia	Greater requirement for B_6 in cats
Pantothenic acid	Anorexia, weight loss	Part of coenzyme A; deficiency is rare
Biotin	Dermatitis	Eggs a rich source
Choline	Neurologic dysfunction, fatty liver	Methyl donor; synthesized in the body
Cobalamin (B_{12})	Anemia (cofactor for energy metabolism)	GI disease may cause deficiency; some of the vitamin is stored.
Folic acid	Anemia, leukopenia	DNA synthesis, bacteria can synthesize
C		Not required

154.6 NUTRITIONAL DEFICIENCIES RESULTING FROM GASTROINTESTINAL DISEASE

Nutritional deficiencies commonly occur as a consequenceof GI disease.[20] Protein and calorie malnutrition is the most common nutritional deficiency in severe or chronic GI disease. Not surprisingly, deficiencies of electrolytes (e.g., sodium, potassium, chloride, and bicarbonate) and divalent cations (e.g., magnesium, zinc, and calcium) are also common and shouldbe corrected.[20] A variety of vitamin deficiencies may occur as a result of severe intestinal disease (Table 154-1). Deficiencies of B vitamins, especially cobalamin, and of some of the fat-soluble vitamins (E and K) are the most common and clinically important micronutrient deficiencies recognized in dogs and cats.[1,7,20] Little is known about deficiencies of microminerals; however, it is reasonable to assume that levels of copper, selenium, zinc, and others may be affected and deficiencies thus corrected by nutritional support.

155 CHAPTER • 155 Nutritional Management of Hepatic Conditions

Rebecca L. Remillard

Korinn E. Saker

The objectives of nutritional therapy in dogs and cats with liver disease are to provide optimal conditions for hepatic repair and regeneration and to prevent or manage complications of hepatic failure, such as hepatic encephalopathy. Hepatic healing and maintenance require a positive caloric balance and nitrogen intake with some consideration given to particular nutrients in certain types of hepatic disease.

155.1 CALORIES AND FEEDING FREQUENCY

The major consequences of malnutrition in any animal are decreased immunocompetence, decreased tissue synthesis and repair, and altered intermediary drug metabolism.[1] The foundation of adequate nutritional management of a dog or cat with hepatic disease is the provision of adequate calories. It is prudent first to provide for the total caloric need and then to consider the protein requirement. When sufficient calories are supplied as fat or carbohydrate, less endogenous or dietary protein is catabolized for energy, resulting in a decrease in the demand to metabolize nitrogen to urea. Enteral nutritional support is preferred to parenteral nutrient administration because it provides antigenic stimulation to the gut-associated lymphoid tissue (GALT) and stimulates secretion of IgA, which helps maintain an intact gut barrier to prevent bacterial translocation into the portal circulation. The method and quantity of food fed must be adjusted according to the animal's ability to handle metabolites. Small, frequent meals (three to six per day) help optimize blood flow through the liver, manage fasting blood glucose, and minimize episodes of hepatic encephalopathy. In the dog, blood glucose concentrations are maintained through glycogenolysis, which begins within 4 to 5 hours of the last meal. The liver exports glucose in order to maintain blood glucose concentrations. In a normal liver, blood glucose concentrations can be maintained through glycogenolysis for another 12 to 28 hours without food. A diseased liver with fewer functioning cells cannot store normal amounts of glycogen and adequately maintain blood glucose concentrations between meals. In the cat, blood glucose concentrations are maintained through gluconeogenesis from fat and protein stores because hepatic glycogen stores are normally minimal. Hepatic glycogen storage in cats is relatively small compared with dogs due to lower glycogen synthase and glucokinase activities. Nonprotein calories should come from highly digestible carbohydrate and fat sources. Most dogs and cats with liver disease can adequately digest and absorb dietary long chain fats; hence, fats should not be routinely restricted unless there is clinical evidence of steatorrhea.

155.2 PROTEIN QUANTITY AND QUALITY AND AMINO ACID PROFILE

Body protein content is not static, but rather is always in a flux between anabolism and catabolism. Protein degradation involves deamination of amino acids. The resulting carbon skeleton is oxidized for energy, and the amino group enters the urea cycle. Under normal metabolic circumstances, about 15% of the daily energy expenditure occurs through the oxidation of amino acids.[2] Protein intake should be balanced with calories consumed. Sufficient calories must be available from fat or glucose before amino acids are used for tissue synthesis and repair. Hence, every effort should be made to minimize protein catabolism in any animal with hepatic disease. Excessive protein feeding requires energy expenditure to rid the body of excess nitrogen, which may not be handled well by the liver and kidneys. Feeding excess nitrogen can result in azotemia or hyperammonemia and accompanying clinical signs of encephalopathy. Conversely, insufficient protein intake has been linked to a low serum albumin concentration, poor immune response, poor healing, and increased risk of

dehiscence and muscle wasting. Hospitalized animals with hepatic disease receiving parenteral nutrition do well clinically with 3 to 5 g of protein per 100 kcal at resting energy requirements (RER). Therapeutic diets well tolerated by dogs contain 3 to 4 g/100 kcal, but feline diets should contain 6 to 7 g/100 kcal. Protein recommendations per 100 kcal of energy are not the same as per kilogram of body weight (BW). Administration of 5 to 6 g of protein on a BW basis delivers 40% more than on a per calorie basis and has resulted in encephalopathic signs in sensitive animals. The protein intake for a particular dog or cat should be adjusted according to the animal's ability to handle these initial protein recommendations.

155.3 VITAMINS, CARNITINE, AND CHOLINE

Water-soluble vitamins are coenzymes that are vital to optimal hepatic metabolism. Folic acid, thiamine, riboflavin, niacin, pantothenic acid, pyridoxine, and B_{12} are essential for hepatic metabolism of glucose, fat, and protein. They are essential coenzymes in the Krebs cycle and for adenosine triphosphate (ATP) production and red blood cell metabolism. They are required in small amounts relative to other nutrients but are required daily and are not optional if tissue energy metabolism is to operate efficiently. These vitamins are easily and inexpensively replaced and should be included in all forms of nutritional support. Few dogs or cats require fat-soluble vitamin supplementation unless there is a history of prolonged weight loss, inappetence, and decreased fat absorption. Animals with long-standing liver disease may benefit from fat-soluble vitamin supplementation because vitamins A, D, and K are primarily stored in the liver. In these cases, it is much simpler and more cost-effective to administer 1 mL of a vitamin A, D, and E product* intramuscularly every 3 to 4 months. Intramuscular or subcutaneous administration of vitamin K_1 (1 to 5 mg/kg body weight/day) may be required for several days.

574

575

Carnitine is an essential cofactor in mitochondrial transport of fatty acids and in subsequent long chain fatty acid beta-oxidation in all cells. Carnitine, residing in the mitochondrial intermembranous space, binds and transports fatty acyl-CoA into the mitochondrial matrix, where beta-oxidation takes place. Carnitine requirements are met by de novo hepatic synthesis using lysine and methionine, but carnitine is viewed as a conditionally essential nutrient when de novo synthesis is inadequate. There is no stated minimum carnitine concentration for pet foods. Beginning in 2002, carnitine supplementation of cat foods was allowed under the regulations of the Association of American Feed Control Officials (AAFCO) at levels not to exceed 1000 ppm on a dry matter basis (DMB).

Choline is an important methyl donor that is required for de novo synthesis of phosphatidyl choline, which is essential in the packaging of very low density lipoprotein (VLDL) in the liver and, therefore, hepatic exportation of triglycerides. A choline deficiency with concurrent lipolysis may slow VLDL export and promote hepatic lipid accumulation. In humans and rats, choline deficiency has been shown to result in tri-acylglyceride (TG) accumulation, depress VLDL synthesis, and cause liver dysfunction.[3] There is clearly a relationship between carnitine and choline. Tissue levels of carnitine are decreased in choline-deficient rats; conversely, adding choline to a choline-deficient diet has been shown to increase hepatic carnitine levels. Although there is evidence and a rationale for the importance of carnitine and choline as separate cofactors in hepatic lipid metabolism, a synergistic relationship may actually be the key. All complete and balanced cat foods should contain at least 60 mg choline/100 kcal, according to AAFCO regulations. Hepatic recovery diets should contain choline and carnitine, although the efficacy levels are not known.

* Vital E-A+D, containing 100 kIU vitamin A, 10 kIU vitamin D, and 300 IU alpha tocopherol per milliliter (Schering-Plough Animal Health Corp., Kenilworth, New Jersey).

155.4 ANTIOXIDANT SUPPLEMENTATION

There is evidence of free radical damage in certain types of liver disease. Two endogenous antioxidant systems exist to scavenge free radicals, a cytosolic system and a membrane-bound system, but they often require a nutritional cofactor. Adding antioxidants to the diet, although the exact effective dose is truly unknown, appears to be reasonable. These “antioxidant” nutrients are known to be part of the body's antioxidant system (directly and indirectly) and may ultimately help minimize the tissue damage. Antioxidant nutrients—vitamin A as beta carotene (5000 IU), vitamin C (250 to 1000 mg), vitamin E as alpha tocopherol (200 to 500 IU), zinc (7.5 mg), selenium (15 µg), copper (1 mg), and manganese (1.5 mg)—are reasonable daily dosages per os with food for a 10 to 30 lb dog or cat. Supplements carrying a United States Pharmacopeia (USP) label are recommended, and the product must be stored at refrigerator temperatures in a container protected from light.

A plethora of herbal remedies have been touted for hepatic patients; however, only two are currently worth consideration: S-adenosyl-L-methionine (SAMe) and milk thistle. Herbal remedies are not nutritional supplements. Taken orally, they should be viewed as compounds with pharmacologic properties.

155.5 NUTRITIONAL CONCERNS IN SPECIFIC HEPATIC CONDITIONS

155.5.1 Feline Hepatic Lipidosis

Hepatic lipidosis (HL), a well-recognized syndrome that occurs in several companion animal species, is characterized by the accumulation of triacylglycerides, which causes hepatic dysfunction and cholestasis. HL historically has been associated with anorectic, obese cats; however, cats with a normal or thin body condition also can be afflicted. Prolonged inappetence is the common denominator, often resulting from a stressful event or occurring secondary to another disease (e.g., diabetes, pancreatitis, cholangiohepatitis). The changes in liver metabolism that occur during HL are similar to those that occur during food deprivation. In the adaptation from the fed to the starved state, fuel usage by the animal shifts from primarily a mixture of fuels to one in which the primary fuel is fatty acids. In cats, lipolysis delivers fatty acids as triglycerides to the liver within hours of fasting because glycogen stores are normally small. The exact metabolic or biochemical aberration or aberrations responsible for the accumulation of fat in the liver during HL are not known. Protein deficiency, lipid oxidation abnormalities, and decreased VLDL exportation are under consideration.

Regardless of the biochemical derangement, it is clear from clinical responses that in feline hepatic lipidosis, adequate caloric and protein intake is the key to recovery. The provision of calories and protein in a complete and balanced formulation, delivered as small, frequent meals or as a continuous rate infusion (CRI), is the only known treatment. Overfeeding must be avoided. Hence, a balanced formulation sufficient to meet the cat's RER (20 kcal/lb BW) at its current weight is a safe starting food dose. However, grossly obese cats with a body condition score of 8/9 or 9/9 may be carrying 35% or more fat; these cats should not be fed at their current body weight, but rather at a lower, estimated optimal weight. If clinical signs of hepatic encephalopathy should begin with feeding, the food dose should be reduced by 50% until signs resolve. Serum phosphorus and potassium levels should be monitored daily during the first few days of refeeding to avoid a clinically relevant decrease caused by the intercellular electrolyte shift that occurs with refeeding. If electrolyte abnormalities occur, the feeding dose should be reduced by 50% and corrective fluid therapy must be instituted. If electrolyte abnormalities persist or become difficult to correct, measurement of and supplementation with magnesium should be considered.

Cats with HL appear to metabolize both enterally and parenterally administered lipids in the form of chylomicrons without exacerbation of clinical signs. The key to the hepatic derangement may lie in the differences between how various types of fat are metabolized in cats. When enteral feeding is not possible due to vomiting or encephalopathy, parenteral nutrition (PN) administration using fat, dextrose, and amino acids (4 g/100 kcal) is possible and should be instituted until a feeding tube can be placed. Fewer (1 g/100 kcal) or no amino acids may be required with hepatic encephalopathy (HE). Administration of a 20% lipid product* at RER through a peripheral catheter for 24 to 48 hours has worked well, as evidenced by improved hepatic serum profiles, when no better feeding alternative is possible. When a feeding tube of any type has been successfully placed, cats with small bowel atrophy due to prolonged anorexia (longer than 5 days) should be fed a monomeric diet with glutamine at RER for the first 24 to 48 hours.† Bolus feeding often can begin as three to six (30 ml) meals per day in a 4.5 kg cat. Initially, feeding via CRI (5 to 10 mL/hour) using a pump or gravity and a liquid product works very well for cats intolerant of bolus feedings and does not cause refeeding diarrhea.‡ 575

576

In cats with HL, the plasma, liver, and skeletal muscle concentrations of carnitine are increased relative to normal cats.[4] Despite this generalized increase in synthesis, the overall carnitine levels attained are still inadequate to meet the body's demands when dietary intake is poor or nonexistent. When a cat is fed enterally, carnitine-supplemented cat foods should be fed to aid the animal's recovery. Choline, like carnitine, may become deficient in anorectic cats; however, the roles of dietary choline and carnitine in feline HL have not been investigated.

155.5.2 Cholangitis, Cholangiohepatitis, Hepatitis, and Cirrhosis

Nutritional strategies are intended to control the complications of hepatic failure. This goal is met by (1) reducing ammonia and ascites formation; (2) compensating for altered dietary lipid, essential fatty acid, and fat-soluble vitamin absorption; and (3) reversing hypoalbuminemia if present.[5] In the refeeding of an anorectic, catabolic animal, provision of calories above the resting energy expenditure, particularly as glucose, may result in metabolic and septic complications.[6] The liver plays a central role in blood glucose homeostasis through the processes of glycogenolysis and gluconeogenesis. Insulin resistance with subsequent glucose intolerance, as evidenced by hyperglycemia, hyperglucagonemia, and hyperinsulinemia, may develop in dogs or cats with liver disease.[7] Liver and, in some cases, muscle glycogen stores are depleted in chronic liver disease, leaving body fat as the main source of energy between meals. In comparison to a dog with normal liver function, glycogen stores may provide substrate only for 10 to 12 hours in a dog with cirrhosis. As a result of impaired glycogen stores, protein catabolism is accelerated.

There is no consensus regarding the level and sources of carbohydrate or fat calories appropriate for patients with compromised liver function. In theory, an adequate supply of highly digestible carbohydrate would reduce muscle and dietary protein catabolism for energy. Provision of at least 30% to 50% of dietary calories as highly digestible grain (cooked starch) is consistent with these metabolic changes. Dextrose should comprise 20% to 40% of the caloric admixture when a dog or cat is supported with PN. Animals with hepatobiliary disease may benefit from fermentable fiber sources. Dietary fiber enables nitrogen fixation by enteric bacteria, reduces the nitrogenous waste substances available for absorption, binds endotoxins and bile salts, and alters the colonic

pH. Dietary soluble fiber can be incorporated into commercial diets using psyllium husk fiber (1 teaspoon per 5 to 10 kg of body weight).[8]

Dietary fats supply a dense form of calories, provide essential fatty acids, and aid in fat-soluble vitamin absorption. Fat is also a palatability enhancer to help inappetent animals. Appropriate dietary fat levels for most animals with hepatic disease range from 15% to 30% DMB. Complications of cholestasis can be associated with reduced excretion of bile salts, resulting in fat malabsorption and steatorrhea.[9] In these cases, dietary fat levels should be lowered. If necessary, an alternate fat source, such as medium chain triglycerides (MCT), could be considered. MCT is reported to be useful for malnourished people with cirrhosis and advanced cholestatic hepatic disease, but reports of clinical trials in animals are not yet available. Therapeutic diets containing MCT can be slowly worked into the diet, which is preferable to adding the oil to food directly. MCT oil alters the palatability of any diet, may result in food refusal, and does not contain essential fatty acids; hence MCT should not exceed 25% of the daily caloric requirement. The inflammatory component of hepatic disease, particularly that associated with hepatitis, may be attenuated by omega 3 (n-3) fatty acid supplementation. Although a specific dosage and the optimal ratio of omega 6 (n-6) to omega 3 fatty acids is not known, n-3 fatty acids have been shown to moderate various aspects of immune cell function. Several therapeutic veterinary diets formulated for the management of liver disease are n-3 enhanced.[10] When parenteral nutrition is necessary, lipid should comprise 60% to 80% of the calories in an admixture.

The liver processes both endogenous and exogenous amino acids; therefore altered protein metabolism may be the most clinically significant metabolic disturbance in an animal with hepatic disease. Increased protein catabolism occurs in early cirrhosis, and protein deficiency generally worsens with progression of liver disease. Addressing the protein needs of an animal with liver disease is a challenge, especially if the pet is critically ill or if signs of HE are apparent. In the absence of HE, protein should not be restricted because many animals with chronic hepatitis or advanced cirrhosis are catabolic and hypoalbuminemic, and most can tolerate standard enteral protein formulas.[11] Protein restriction and an increased branched chain to aromatic amino acid ratio should be limited to HE patients and those clinically unable to tolerate standard formulations.

Most therapeutic diets formulated for the management of dogs and cats with liver disease have a lower protein content (14% to 18% DMB) than the maintenance level (20% to 34% DMB). Recommendations on specific dietary protein concentrations have significant limitations. As the biologic value of a protein increases, less total protein is required to meet the amino acid requirements of the patient. In non-HE patients, a starting range for dietary protein would be 18% to 30% DMB. A more restricted protein level (8% to 15%, DMB) may be required for dogs exhibiting signs of HE postprandially. In all cases, protein ingredients of high biologic value (HBV) should be used so that the total nitrogen consumed may be minimized. Supplementation of the diet with HBV protein sources (e.g., cooked egg whites) provides essential amino acids while minimizing nitrogenous metabolites. It has been recommended that the proportion of branched chain amino acids (BCAA) to aromatic amino acids (AAA) be high in those diets. As liver disease progresses, the plasma concentration of BCAA decreases and AAA increases, because peripheral organs use BCAAs as a source of energy. There is increased cerebral uptake of AAAs, which may promote encephalopathy via synthesis of false neurotransmitters. To date, no data exist to suggest that BCAA formulations are superior to standard AAA formulations for animals with liver disease except when HE is present. Although dogs normally can synthesize sufficient amounts of taurine, in the case of severely compromised liver function, supplementation (250 to 500 mg/day) may be beneficial to choleresis. Additionally, taurine has some antioxidant action, which can help ameliorate the damage associated with excessive oxidative stress in liver disease.

Vitamin deficiency is common in chronic liver disease. The water-soluble B vitamins can be lost through vomiting or urinary losses or can become deficient as a result of anorexia, intestinal malabsorption, or

decreased hepatic metabolism. High daily B vitamin intakes are recommended for patients with chronic forms of hepatic disease because excesses are excreted in the urine.* Nutrient malabsorption and the increased amounts of unconjugated bile salts associated with cirrhosis primarily alter absorption of fat-soluble vitamins, because absorption of vitamins A, D, E, and K depends on the availability of bile salts.

Gastrointestinal ulceration and hemorrhage associated with chronic hepatitis may result in iron (Fe) deficiency. 576
This deficiency can be addressed by altering dietary Fe concentrations or with oral supplementation or 577
injectable Fe solutions. Supplementation should be approached with caution, because hemosiderosis is observed when liver disease has an inflammatory component; the hepatic Fe concentration should be assessed prior to supplementation. Diets supplying 80 to 140 ppm DMB of Fe should be adequate to meet daily Fe requirements. A zinc (Zn) deficiency results in abnormal ammonia metabolism, but diets containing more than 200 ppm DMB of Zn should be adequate. Diets can be supplemented with Zn gluconate (3 mg/kg body weight/day) or Zn sulfate (2 mg/kg body weight/day) divided into three doses. In cases of advanced hepatocellular damage with hypoalbuminemia and ascites, sodium restriction (0.01% to 0.25% DMB), with chloride at 1.5 times sodium, is recommended to help manage fluid balance and portal hypertension.

* B-Vitamin Complex, containing 50 mg thiamine, 2 mg riboflavin, 100 mg niacin, 2 mg pyridoxine, 10 mg pantothenic acid, and 0.4 ppm B_{12} per milliliter (Butler Co., Columbus, Ohio).

155.6 COPPER-ASSOCIATED HEPATOTOXICOSIS

Copper (Cu) storage disease impairs biliary excretion of Cu, resulting in signs of Cu toxicosis. The condition has been identified in the Bedlington terrier breed and is considered the canine counterpart of Wilson's disease in humans. These homozygous recessive individuals accumulate excessive amounts of Cu in the hepatocytes. If the condition is left untreated, the life expectancy is only 3 to 7 years.[12] With DNA technology, affected dogs can be identified and dietary changes can be initiated early in the disease process. The predominant feature is the progressive accumulation of Cu in hepatocytes, with hepatotoxicosis occurring at 2000 µg/g DMB. The time course can be as short as 8 to 12 weeks after birth, or Cu may accumulate for up to 1 year before clinical signs of toxicity become evident. Definitive diagnosis of Cu-associated hepatotoxicosis requires histochemical staining and quantitative assay of Cu in a liver biopsy sample.[13] Non-Bedlington terriers, cocker spaniels, and Doberman pinschers also can accumulate excess Cu in hepatocytes. Whether elevated hepatic Cu is the cause or consequence of the documented hepatitis and cirrhosis reported in these patients is not yet clear.

Copper-associated hepatotoxicosis is managed by feeding a low Cu diet and use of Cu-chelating agents. The AAFCO recommends 7.3 to 250 ppm DMB of Cu in both growth and maintenance canine foods. Therapeutic veterinary diets designed for liver patients contain 3 to 5 ppm DMB copper. Vitamin C and zinc supplementation are often used with copper hepatotoxicosis. Ascorbic acid augments urinary excretion of Cu and Zn and induces synthesis of intestinal metallothionein, which, because it has a much greater affinity for Cu than for Zn, binds excess dietary Cu. Elemental Zn can be supplemented in the acetate, sulfate, gluconate, or methionine forms. The recommended loading dose is 100 mg of elemental Zn per os given biweekly for 3 weeks, followed by a maintenance dose of 50 mg per os twice daily. Zn supplementation should be given between meals in a small amount of food to decrease the nausea and vomiting side effects.

156 CHAPTER • 156 Nutritional Management of Endocrine Diseases

Kathryn E. Michel

With the exception of diabetes mellitus, the role of diet in the management of endocrine disorders of dogs and cats is largely uninvestigated. When abnormalities related to nutrient metabolism are seen, treatment of the primary endocrinopathy usually resolves the problem. Most of this chapter deals with the use of diet as a means of enhancing glycemic control in diabetics. A brief mention is made of dietary considerations in the management of endocrinopathy-associated hyperlipidemia and insulinomas.

156.1 DIABETES MELLITUS

With few exceptions, dietary management of diabetes mellitus in dogs and cats is done in conjunction with insulin or other pharmacologic treatment. Therefore it is important to stress that although appropriate dietary therapy can improve glycemic control, emphasis should be placed on adjustment of the insulin (or oral hypoglycemic) dosage and schedule and control of concurrent diseases. The objectives of dietary management of these animals are establishing and maintaining an optimal body weight, integrating feeding and insulin injection schedules, and optimizing glycemic control through diet composition. Beyond these goals, it is important to recognize that no single diet or dietary regimen fits all or even the majority of cases. To arrive at an appropriate dietary regimen, the practitioner must evaluate each dog or cat based on its body condition, on insulin therapy, and on whether coexisting diseases are a factor. Once a regimen is in place, it is critical that it be adhered to it as closely as possible, because alterations affect the efficacy of insulin therapy.

156.1.1 Body Condition

Obese dogs and cats can show insulin resistance that may resolve with weight loss.[1,2] In some cats with diabetes, the condition resolves naturally once loss of excess weight has been achieved. Many diabetic animals first have some form of medical crisis. Often, they have excess body fat but at the same time have also had some degree of muscle wasting. It is important that these animals be stabilized before any kind of caloric restriction for weight reduction is instituted. Many diabetic animals are underweight when first examined; after they have been stabilized, they should be fed a modest increase in calories to promote repletion.

156.1.2 Meal Timing and Diet Composition

The timing of meals is necessarily linked to the insulin dosage schedule. Ideally, the feeding timetable and the diet composition promote slow, steady absorption of nutrients from the gastrointestinal tract at times of peak insulin activity. Complex carbohydrates are generally absorbed in this fashion and should provide 50% to 60% of the calories in diets for canine diabetics. Soft, moist pet foods should be avoided, because they contain a high proportion of simple sugars.

Cats have evolved eating relatively little dietary carbohydrate. There are two major factors in which cats differ from more omnivorous species in their response to a carbohydrate-containing meal. The first is the lack of inhibition of hepatic gluconeogenesis. The activity of key gluconeogenic enzymes does not alter in the fed or fasted state, so that glucose will be synthesized from precursors, such as amino acids and glycerol, regardless of the extent of dietary carbohydrate intake. The second feature unique to feline carbohydrate metabolism is the lack of the enzyme glucokinase in both hepatic tissues and pancreatic islet cells. The maximal rate of this

enzyme occurs when glucose concentrations are elevated; this facilitates the uptake and metabolism of glucose postprandially, both by serving as the "glucosensor" of the pancreatic beta cell for the release of insulin and by initiating the metabolism of glucose in the liver.

Some preliminary clinical trials have investigated the use of low-carbohydrate diets in diabetic cats.[3] The results have been encouraging, with the majority of cats responding with improved clinical signs, decreased insulin requirements (with some cats no longer requiring any insulin therapy at all), and improved serum glucose curves and fructosamine concentrations. One problem with interpreting the results of these investigations is the difficulty encountered in differentiating cats with insulin-dependent diabetes and those with transient disease. It may be that this type of dietary therapy is more or less indicated in a given cat, depending on the form of diabetes mellitus the animal has.

Increased dietary fiber has been recommended as an adjunct therapy for managing diabetes mellitus in dogs and cats. This recommendation was based largely on clinical studies involving humans, in whom fiber seems to aid in glycemic control by modulating glucose absorption from the gastrointestinal tract. There is a limited amount of experimental and clinical research involving dogs and one clinical trial in cats that suggest that high-fiber diets may aid in glycemic control in these species as well. Most of the data in human studies pointed to soluble fibers as being the effective fiber type for modulating glucose absorption. However, there is evidence that insoluble fibers are also effective in improving glycemic control in dogs with naturally occurring diabetes mellitus.[4] One published clinical trial investigating diabetic cats showed some benefits from feeding a diet that contained insoluble fiber over a low-fiber diet.[5] The diets also differed somewhat in protein and carbohydrate content (the fiber-containing diet was higher in protein and lower in carbohydrates). It is not entirely clear whether the improved glycemic control when cats consumed the fiber-containing diet was attributable to the fiber, the macronutrient makeup of the diet, or a combination of the two. Therefore currently there is no proven rationale for placing a nonobese diabetic cat on a commercial high-fiber diet.

It must be stressed that uniform caloric intake and normalization of body condition take precedence over the use of fiber-containing diets in the management of this disease. Many of the fiber-containing diets on the market today have been formulated as calorically restricted for the purpose of weight control and therefore would be contraindicated in an underweight or debilitated patient. In addition, "fiber" is a generic term, and one cannot simply expect any diet with additional fiber or even a specific category of fiber (e.g., insoluble, fermentable) to have the same physiologic effects a particular diet had in an investigation. Furthermore, increasing the amount of fiber in a diet generally decreases the digestibility and absorption of most nutrients. Many high-fiber diets are fortified with minerals and protein, but beyond the results of basic maintenance feeding trials conducted by the Association of American Feed Control Officials, data are lacking on the effects of these diets on nutrient availability. Caution should be used when supplementing a diet with fiber. If the diet contains marginal amounts of nutrients with respect to the nutritional requirements of the pet eating the diet, the addition of fiber may lead to deficiency of one or more nutrient.

156.1.3 Role of Ultra-Trace Elements

A brief mention should be made of the role of the ultra-trace elements chromium and vanadium in the management of canine and feline diabetes mellitus. Chromium appears to be involved in the maintenance of glucose tolerance. True dietary chromium deficiency has not been documented in companion animals. To date, clinical trials investigating whether pharmacologic amounts of chromium might improve glycemic control in diabetic dogs and cats are inconclusive.[6] Vanadium, when dosed in pharmacologic amounts, has insulin-like effects. Again, clinical trials in dogs and cats are lacking; however, vanadium has been documented to cause

gastrointestinal side effects when administered orally, and chronic excessive intake may have toxic effects.[6] This element therefore should be used with caution.

156.2 HYPERLIPIDEMIA

A number of endocrinopathies can be associated with hyperlipidemia, including diabetes mellitus, hypothyroidism, and hyperadrenocorticism. Depending on the primary condition, hypertriglyceridemia, hypercholesterolemia, or both may be present. In general, therapy should be directed toward managing the underlying disease. Successful treatment often results in resolution of this condition. In some instances, dietary management can be used as an adjunctive therapy. The current diet should be evaluated, and if greater than 30% of the calories come from fat, a trial with a lower fat food should be considered.

156.3 INSULINOMA

Dietary therapy may aid in the management of the clinical signs that accompany an insulinoma. The goal is to minimize hypoglycemia by providing a highly digestible diet that contains low to moderate amounts of complex carbohydrates (as opposed to simple sugars and highly digestible starches) and to divide the daily feeding portion into three to six meals administered throughout the day. If signs of hypoglycemia do occur, the pet should be fed immediately and, if possible, foods or solutions containing simple carbohydrates should be avoided, because these may overstimulate the tumor and lead to another episode of hypoglycemia a short time later.

157 CHAPTER • 157 Nutritional Modulation of Heart Disease

Lisa M. Freeman

John E. Rush

The goal of nutrition is no longer just to prevent deficiencies. It is now known that modification of diet can be an important part of medical therapy for heart disease. In the 1960s, the main nutritional recommendations for dogs with congestive heart failure (CHF) were to feed a low-sodium diet (for all stages of heart disease), to feed a restricted protein diet, and to provide supplemental B vitamins.[1] Few changes to these recommendations were made until the 1980s, when the question of how early to institute sodium restriction was raised and one of the first mentions of cardiac cachexia appeared in veterinary medicine.[2] It was also in the late 1980s that the discovery of the relationship between taurine deficiency and feline dilated cardiomyopathy (DCM) was published.[3] Now, research is beginning to show that nutrition may be able to modulate heart disease, either by slowing the progression, minimizing the number of medications required, improving quality of life or, in rare cases, actually curing the disease. There is potential for the use of diet as an important adjunct to medical therapy for animals with heart disease.

The main goals of diet therapy for heart disease are to maintain optimal body weight, to avoid nutritional deficiencies and excesses, and to take advantage of the potential benefits of pharmacologic doses of certain nutrients.

157.1 OPTIMAL WEIGHT MAINTENANCE

A key goal for the optimal management of heart disease is to maintain optimal body weight, because both obesity and weight loss can adversely affect health.

157.1.1 Obesity

Some patients with heart disease are overweight (i.e., over ideal body weight) or obese (i.e., more than 20% over ideal body weight). Endocrine disease, such as hypothyroidism and Cushing's disease, can be risk a factor for obesity and should be ruled out as an underlying cause; however, most obese animals simply suffer from overeating. Obesity has adverse effects on cardiac output, pulmonary function, neurohumoral activation, blood pressure, and heart rate in people and in experimental animal models, therefore it is likely to be similarly deleterious for companion animals with heart disease.[4] Owners often find that severely obese dogs and cats with cardiac disease that successfully lose weight appear less dyspneic and more active.

Successful weight reduction is a difficult and often unsuccessful endeavor. A careful dietary history is necessary to determine and control all sources of caloric intake as part of a successful weight loss program. Typically, the pet food is only one source of calories for the pet, and as many or more calories may be coming from treats and table food.[5] Additional sources of calories can be food intended for other household pets or food given by other people in the house, neighbors, or people delivering mail or packages. Because diets that are marketed as being reduced calorie vary tremendously in their caloric density, it is important to recommend a specific pet food and amount based on caloric requirements for weight loss, rather than making the general recommendation to switch to a “reduced calorie” pet food. Also, veterinarians should recommend a specific type and number of treats that can be fed to avoid overindulgence. Nonstarchy vegetables (fresh, frozen, or canned forms labeled “no salt added”) are excellent, low-calorie treats for dogs that are obese and have heart disease. The practitioner should recheck the animal's body weight after 2 weeks on the diet, and if the animal is

not losing weight, the owner should be questioned to find other potential sources of calories. If compliance appears to be good, the amount of food should be reduced further. The animal should be weighed every 2 weeks until consistent weight loss is achieved (1% to 2% per week) and then once monthly until the goal weight is achieved.

157.1.2 Cachexia

Cardiac cachexia is the muscle wasting commonly seen in patients with CHF. In one study of dogs with DCM, more than 50% of patients had some degree of cachexia.[6] The weight loss that occurs in animals with CHF is unlike that seen in a healthy dog or cat that loses weight. In a healthy animal receiving insufficient calories to meet requirements, metabolic adaptations allow fat to be used as the primary fuel source, thus preserving lean body mass. Conversely, the primary fuel source in animals with an acute or chronic disease, including heart disease, is amino acids from muscle, therefore these animals quickly catabolize muscle and lean body mass. Thus the distinguishing feature of cachexia is a loss of lean body mass, which has direct and deleterious effects on strength, immune function, and survival.[7] Cachexia is often mistakenly viewed as an end-stage syndrome manifested by an emaciated dog or cat. In fact, cachexia is a slowly progressive process of muscle loss that can be very subtle initially and can even occur in an obese animal. Recognizing the process of cachexia at an early stage may provide better opportunities to manage it effectively.

The loss of lean body mass in cardiac cachexia is a multifactorial process caused by anorexia, increased energy requirements, and metabolic alterations.[7] The anorexia may be secondary to fatigue or dyspnea or may be due to medication toxicity or feeding of an unpalatable diet.[7] Anorexia is present in 34% to 75% of dogs with heart disease.[5,8] However, increased production of inflammatory cytokines, such as tumor necrosis factor (TNF) and interleukin-1 (IL-1), is the primary mediator of cachexia.[7] These inflammatory cytokines are known to directly cause anorexia, to increase energy requirements, and to increase the catabolism of lean body mass. Of particular pertinence to heart disease, TNF and IL-1 also cause cardiac myocyte hypertrophy and fibrosis and have negative inotropic effects.

Cardiac cachexia is typically recognized only after CHF has developed. It is more common in dogs than in cats and is most often seen in DCM or right-sided heart failure. Loss of lean body mass is most readily evident in the epaxial, gluteal, scapular, or temporal muscles. Nutritional considerations for cardiac cachexia should include management of anorexia, if present. Nutritional modulation of cytokine production also may be helpful. One method of decreasing the production and effects of cytokines is omega 3 (n-3) polyunsaturated fatty acid supplementation (see below). Supplementation of fish oil, which is high in n-3 fatty acids, can decrease cytokine production in dogs with CHF and improve cachexia.[6] In some but not all dogs with CHF-induced anorexia, fish oil supplementation can improve food intake.[6] In addition, reduction of cytokines has been correlated with survival in dogs with CHF.[6]

579 580

157.2 MODULATION OF SPECIFIC NUTRIENTS

Nutritional deficiencies once were a common cause of cardiac disease in people and probably animals. In cats, taurine deficiency was a common cause of heart disease until as recently as the late 1980s. Identifiable nutritional deficiencies are now uncommon in dogs and cats but still could play a role in the etiology of some heart diseases. Nutritional deficiencies also may develop secondary to the disease or its treatment. A new area of nutritional research is that of nutritional pharmacology, the concept that supplementation of certain nutrients may provide benefits above and beyond their known nutritional effects. Therefore modulation of various nutrients by reducing

or increasing their intake (either a small amount or to pharmacologic levels) may be recommended for animals with heart disease.

157.2.1 Protein and Taurine

157.2.1.1 Protein

In the 1960s authors recommended a restricted protein intake for dogs with CHF to prevent "metabolic stress" on the kidneys and liver.[1] There is no evidence that protein restriction is necessary for dogs and cats with CHF and, in fact, it probably is deleterious, because these patients are predisposed to loss of lean body mass. Many of the diets designed for dogs with cardiac disease are low in protein (3.6 to 4.2 g/100 kcal), and protein-restricted diets designed for renal disease are often recommended for animals with heart disease. Unless severe renal dysfunction is present (i.e., serum creatinine >3.0 g/dL), high-quality protein should be fed to meet canine (5.1 g/100 kcal) and feline (6.5 g/100 kcal) minimum levels according to Association of American Feed Control Officials (AAFCO).[9]

157.2.1.2 Taurine

Taurine is an amino acid found in high levels in the myocardium. Despite our knowledge of the role of taurine deficiency in feline DCM, a small number of cats still develop DCM.[3] Most current cases of feline DCM do not involve taurine deficiency, but it should be suspected in all cases of this disorder. A dietary history should be elicited from owners to determine whether the cat has been fed a poor quality, homemade, vegetarian, or otherwise unbalanced diet. Plasma and whole blood taurine levels should be measured, and treatment with taurine (125 to 250 mg given orally twice a day) should begin concurrently with medical therapy. If the taurine concentration is found to be normal, taurine supplementation can be discontinued.

Unlike cats, dogs are able to synthesize adequate amounts of taurine, which is not considered a requirement for canine diets. Most dogs with DCM do not have taurine deficiency, but low taurine concentrations have been found in some dogs with the disorder, particularly breeds in which DCM is not a common disease.[10] The most common breeds in which DCM has been reported to be associated with taurine deficiency are the American cocker spaniel, golden retriever, Labrador retriever, Newfoundland, Dalmatian, and English bulldog.[10–12] In one small study, cocker spaniels supplemented with taurine and carnitine showed clinical and echocardiographic improvement.[13] It is not known whether the response would be similar with either taurine or carnitine alone.

Taurine deficiency in dogs may be related to dietary factors, because it is thought to be more common in dogs eating high-fiber or certain lamb meal and rice-based diets. Taurine deficiency also may be the result of increased renal or fecal loss of taurine or other metabolic defects present in certain breeds. In a study of Portuguese water dog puppies, plasma taurine was low in all puppies tested, and DCM was diagnosed in eight of nine puppies.[14] Taurine supplementation was instituted in six of the puppies, and this significantly increased both circulating taurine concentrations and cardiac function.[14] A recent study showed that a low-taurine, very low protein diet fed to beagles for 48 months caused decreased whole blood taurine concentrations, and DCM developed in one of 16 dogs.[15]

In the authors' experience, although some dogs of atypical breeds with DCM have low circulating taurine concentrations, not all of them respond to taurine supplementation. In one small retrospective study, dogs

that were taurine deficient and supplemented with taurine (with or without carnitine) did not show a significantly different response from that of dogs with DCM that were not taurine deficient and were not supplemented with taurine.[11] Dogs with DCM and taurine deficiency that respond to taurine supplementation generally do not have as dramatic a response as do taurine-deficient cats with DCM. Nonetheless, measurement of plasma and whole blood taurine concentrations is warranted in cocker spaniels and some other breeds of dogs with DCM. Supplementation with taurine (500 mg give orally two or three times a day), with or without carnitine (1 g given orally two or three times a day), is recommended in dogs with documented taurine deficiency. Some of the potential benefits of taurine in dogs with DCM may be due to the amino acid's positive inotropic effects or to its role in calcium regulation in the myocardium.

The AAFCO minimum for taurine for adult cats is 25 mg/100 kcal for dry food and 50 mg/100 kcal for canned foods.[9] Because taurine is a nonessential nutrient in dogs (i.e., it is not thought to be required in the diet), no minimum level has been established for commercial dog foods. The dietary taurine content of commercial dog foods, based on manufacturers' information, varies widely (less than 5 to over 50 mg taurine/100 kcal). To achieve a dose of 500 mg every 12 hours for a 40 kg dog (although this has not been determined to be the *optimal* dose of taurine for a dog with DCM), a diet would have to contain approximately 50 mg/100 kcal of taurine.

157.2.2 Fat

Fat provides calories and increases the palatability of pet foods, but it also can significantly affect immunologic, inflammatory, and hemodynamic parameters. The n-3 fatty acids, eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), are long chain fatty acids in which the first double bond is at the position of the third carbon from the methyl end (in the omega 6 [n-6] polyunsaturated fatty acids [i.e., linoleic, gamma linolenic, and arachidonic acids], the first double bond is at the sixth carbon). This minor chemical difference gives a different structure and characteristics to the fatty acid. Plasma membranes normally contain very low concentrations of n-3 fatty acids, but levels can be increased by a food or supplement enriched with n-3 fatty acids. Dogs with CHF have been shown to have plasma fatty acid abnormalities, including decreased concentrations of EPA and DHA, compared to normal dogs.[6,16] In one study of dogs with DCM and CHF, fish oil supplementation normalized these plasma fatty acid abnormalities.[6]

580

581

Another potential benefit of n-3 fatty acid supplementation is that breakdown products of the n-3 fatty acids (series 3 and 5 eicosanoids) are generally less potent inflammatory mediators than eicosanoids derived from n-6 fatty acids (series 2 and 4 eicosanoids). This decreases the production of cytokines and other inflammatory mediators, which may reduce cachexia.[6] The authors currently recommend a dosage of 40 mg/kg EPA and 25 mg/kg DHA for dogs and cats with anorexia or cachexia. With the exception of a few specially designed therapeutic diets, commercial diets do not achieve this level of n-3 fatty acids, therefore supplementation is usually necessary. Because the amount of EPA and DHA in individual fish oil supplements varies widely, it is important to know the exact amount in the brand of supplement recommended. The most common formulation of fish oil, however, is 1 gram capsules that contain approximately 180 mg EPA and 120 mg DHA; these can be purchased over the counter at most human pharmacies or health food stores. At this concentration, fish oil can be administered at a dose of 1 capsule per 10 pounds of body weight to achieve the authors' recommended EPA and DHA dosage. Fish oil with higher concentrations of EPA and DHA can be obtained from medical supply catalogs and may be more feasible for large dogs. Fish oil supplements should always contain vitamin E as an antioxidant, but other nutrients should not be included to avoid toxicities. Cod liver oil and flax seed oil should not be used as sources of n-3 fatty acids.

157.2.3 Minerals

157.2.3.1 Sodium

Even before clinical signs become apparent in cardiac disease, the renin-angiotensin-aldosterone (RAA) system is activated and sodium excretion is reduced. Based on this knowledge, authors in the 1960s and 1970s recommended changing to a severely sodium-restricted diet when a heart murmur was first detected, even before clinical signs were present. However, dietary sodium restriction can further activate the RAA system, therefore it is not clear whether sodium restriction in early heart disease is beneficial or harmful.[17] A study of low-sodium diets in dogs with CHF showed that measures of cardiac size decreased significantly on a low-sodium diet compared with a moderate-sodium diet, especially in dogs with chronic valvular disease, but the effect of low-sodium diets on survival was not studied.[16]

The optimal time to institute sodium restriction and the degree of sodium restriction is not known, but severe sodium restriction (i.e., near the AAFCO minimum of 20 mg/100 kcal for dogs and 50 mg/100 kcal for cats) is not currently recommended for early heart disease. For an animal with heart disease without CHF (e.g., a dog with chronic valvular disease with no clinical signs or an asymptomatic cat with hypertrophic cardiomyopathy), the authors recommend that the animal be fed a mildly sodium-restricted diet (i.e., sodium content less than 100 mg/100 kcal) and that the owner be instructed to avoid giving the pet high-sodium treats or table food. Most owners are unaware of the sodium content of pet foods and human foods and need very specific instructions regarding appropriate foods and acceptable low-salt treats (Table 157-1). When CHF first arises, additional sodium restriction is recommended (i.e., less than 80 mg sodium/100 kcal). This can be achieved with a therapeutic diet designed for animals with early heart disease or with some diets designed for use in older dogs.

If a diet designed for senior dogs is used, the characteristics of the individual product must be examined. There is no legal definition for a senior diet, therefore the levels of calories, protein, sodium, and other nutrients can vary dramatically. Diets designed for animals with renal disease are not recommended for most cardiac patients because of the protein restriction (unless severe renal dysfunction is present). As CHF becomes more severe, more sodium restriction may allow lower dosages of diuretics to be used to control clinical signs. To achieve severe sodium restriction, it is usually necessary to feed a commercial therapeutic diet designed for cardiac patients. Typically, these diets are severely restricted in both sodium and chloride; levels of other nutrients vary with the individual product.

Table • 157-1 Examples of Low-Sodium Treats*

PRODUCT	kcal/Sodium (treat)/ (mg/treat)
Dog Treats	
Science Diet Senior Treats (medium)	20/13
Milk-Bone Super Premium Chicken Meal & Rice Flavored Biscuits	10/10
Iams Original Formula Biscuits (small)	22/10
Hill's Prescription Diet Canine Treats	13/5
Stewart Fiber Formula Dog Biscuits (medium)	25/5
Baby carrots	4/4
Alpo Healthy Snacks Variety Snaps with Real Meat	13/6
Apple (raw, 1 slice) or orange (1 section)	10/0
Cat Treats	
Essentials Brand Overall Health for Cats	2/3
Purina Whisker Lickin's Crunchy Cat	2/2
Treats—Tartar Control (all flavors) Stewart Fiber Formula Cat Treats	1/1
Treats to Avoid	
Baby food; pickled foods; bread; pizza; condiments (e.g., ketchup, soy sauce); lunch meats and cold cuts (e.g., ham, corned beef, salami, sausages, bacon, hot dogs); most cheeses, including "squirtable" cheeses (unless specifically labeled as low sodium); processed foods (e.g., potato mixes, rice mixes, macaroni and cheese); canned vegetables (unless labeled as no salt added); snack foods (e.g., potato chips, packaged popcorn, crackers); soups (unless homemade without salt); and most other pet treats.	

* Even low-sodium treats, if fed in large quantities, can provide a large dose of sodium (this especially can be a problem in cats or small dogs).

157.2.3.2 Potassium

Hypokalemia causes muscle weakness, predisposes patients to digitalis toxicity, and potentiates arrhythmogenesis. In addition, Class I antiarrhythmic drugs (e.g., procainamide, quinidine) are relatively ineffective in the face of hypokalemia. Hypokalemia can be precipitated by the use of loop diuretics (e.g., furosemide), thiazide diuretics (e.g., hydrochlorothiazide), or by inadequate dietary intake (often associated with anorexia). In the past, when the mainstays of therapy were diuretics and digoxin, hypokalemia was recognized as a significant problem in people and dogs with CHF.

Angiotensin-converting enzyme (ACE) inhibitor therapy has gained widespread use in the management of dogs with CHF, and this class of drug results in renal potassium sparing. ACE inhibitors cause an increase in serum potassium, and some animals develop hyperkalemia. Spironolactone, now used in some dogs and cats with heart disease, is an aldosterone antagonist and a potassium-sparing diuretic. Animals receiving ACE inhibitors and/or spironolactone can develop hyperkalemia, particularly if they eat a diet that contains high levels of potassium. Because some commercial cardiac diets contain higher potassium concentrations to counteract the theoretical potassium loss due to diuretics, these diets can contribute to hyperkalemia.

581
582

Commercial diets vary widely in potassium concentrations. Commercial reduced-sodium diets for dogs can have 143 to 381 mg potassium/100 kcal (the AAFCO minimum is 170 mg/100 kcal).[9] Commercial feline reduced-sodium diets can have 152 to 362 mg potassium/100 kcal (AAFCO minimum of 150 mg/100 kcal).[9] If hyperkalemia is present in a dog or cat with heart disease, a diet with a lower potassium content should be selected. Conversely, if an animal is hypokalemic, a diet higher in potassium may be indicated, or oral potassium supplementation may be instituted.

157.2.3.3 Magnesium

Magnesium plays an important role in normal cardiac function. Alterations in magnesium homeostasis can occur in people and dogs and can have deleterious effects in a variety of cardiovascular conditions, including hypertension, coronary artery disease, congestive heart failure, and cardiac arrhythmias. Some cardiac drugs, including digoxin and loop diuretics, are associated with magnesium depletion. Therefore animals with heart failure receiving these medications have the potential to develop hypomagnesemia. Hypomagnesemia can increase the risk of arrhythmias, decrease cardiac contractility, cause muscle weakness, and contribute to renal potassium loss and can potentiate the adverse effects of certain cardiac medications. Hypomagnesemia has not been a consistent finding in studies of animals with heart disease, but this may be because serum magnesium concentrations are a poor indicator of total body stores.[16,18,19] Therefore a normal serum magnesium level does not necessarily mean there are adequate total body stores. We currently recommend routine measurements of serum magnesium, especially in animals with arrhythmias or those on large doses of diuretics.

As with potassium, magnesium concentrations vary widely in commercial pet foods. Commercial reduced-sodium diets for dogs can have 9 to 40 mg magnesium/100 kcal (AAFCO minimum of 10 mg/100 kcal).[9] Commercial feline reduced-sodium diets can have 8 to 69 mg magnesium/100 kcal (AAFCO minimum of 10 mg/100 kcal).[9] A diet high in magnesium would be indicated for an animal with a low serum magnesium concentration. In some animals with low serum magnesium concentrations, diet adjustment alone does not correct the problem, and oral supplementation is required.

157.2.4 Vitamins

157.2.4.1 B Vitamins

Thiamine deficiency is known to be a cause of cardiomyopathy in humans, but there has been little investigation into the role of B vitamin deficiency as a cause of heart disease in dogs and cats. Anorexia and urinary loss of water-soluble vitamins can contribute to low B vitamin concentrations in patients with heart failure. Thiamine has been the B vitamin studied in greatest detail. In one study, more than 90% of people with CHF had low thiamine concentrations.[20] As with other nutrients, such as potassium, B vitamin deficiencies may have been much more common when furosemide was the primary means of therapy for patients with CHF. Recent research has shown that vitamin B_{12}, but not vitamin B_6 or folate, was significantly lower in cats with cardiomyopathy than in healthy controls, an effect that was unrelated to diet or furosemide use.[21] Based on information from other species, however, animals with cardiac disease (at least those receiving diuretics) may have higher B vitamin requirements. Most commercial cardiac diets have increased amounts of water-soluble vitamins to offset urinary losses, therefore supplementation usually is not required.

157.2.5 Other Nutrients

157.2.5.1 Carnitine

L-carnitine is concentrated in skeletal and cardiac muscle and is critical for fatty acid metabolism and energy production. Carnitine deficiency has been associated with primary myocardial disease in a number of species, including a family of boxer dogs.[22] Anecdotal reports exist regarding the efficacy of carnitine in canine DCM, but no blinded prospective studies have been done, therefore a causative role has not been established. Even if carnitine deficiency is not the inciting cause of DCM, carnitine supplementation could be beneficial by improving myocardial energy production. In human DCM patients, most studies of carnitine have not been well controlled. However, one randomized, double-blind, placebo-controlled study showed improved 3-year survival in human DCM patients receiving 2 g/day of carnitine.[23] It is not yet clear whether the carnitine deficiency seen in some dogs with DCM is the cause of the disease or occurs secondary to the development of CHF. A study of rapid pacing–induced heart failure in dogs showed that myocardial concentrations decreased in normal dogs after the onset of CHF.[24] Carnitine supplementation has few side effects, but the high cost is a deterrent for some owners. We currently offer the option of carnitine supplementation (50 to 100 mg/kg given orally every 8 hours) to owners of dogs with DCM.

157.2.5.2 Antioxidants

Much attention has been given to antioxidants for their potential role in the prevention and treatment of human cardiac diseases. Reactive oxygen species are a by-product of oxygen metabolism, for which the body normally compensates through the production of endogenous antioxidants. An imbalance between oxidant production and antioxidant protection, however, could increase the risk of heart disease. Antioxidants are produced endogenously but also can be supplied exogenously. The major antioxidants include enzymatic antioxidants (e.g., superoxide dismutase, catalase, glutathione peroxidase) and oxidant quenchers (e.g., vitamin C, vitamin E, glutathione, and beta carotene). Most of the research in human cardiology has been done on coronary artery disease; however, in dogs with DCM and CHF, oxidative stress increases and vitamin E concentrations decrease with more severe disease.[25] Additional research is required, but antioxidant supplementation may hold promise as a component of therapy for animals with heart disease.

157.2.5.3 Coenzyme Q10

Coenzyme Q10, like carnitine, is a cofactor in a number of reactions required for energy production; however, it also is an antioxidant. Although coenzyme Q10 supplementation has anecdotally been reported to be beneficial, controlled prospective studies are necessary to judge the efficacy of this product accurately. Most human studies of coenzyme Q10 supplementation have not been well controlled, and the results are conflicting. One study of experimentally induced CHF in dogs showed that serum coenzyme Q10 levels were not reduced in dogs with CHF.[26] Coenzyme Q10 supplementation increased serum, but not myocardial, concentrations in one canine study.[26] The current recommended dose in dogs is 30 mg given orally twice a day, although a dose of up to 90 mg given orally twice a day has been recommended for large dogs. Possible reasons for the purported benefits of supplementation include correction of a deficiency, improved myocardial metabolic efficiency, or increased antioxidant protection.

157.3 PRACTICAL ASPECTS OF FEEDING THE PATIENT WITH HEART DISEASE

There is no single “best” diet for managing heart disease. It is important to match the nutritional needs of an individual patient to the diet or diets that best suit those needs. Patients with heart disease vary in terms of clinical signs, laboratory parameters, and food preferences, all of which affect diet selection. For example, animals with asymptomatic heart disease require less severe sodium restriction than animals with CHF. Dogs with cardiac cachexia require a calorically dense diet, whereas an overweight dog should be fed a calorically restricted diet. Concurrent diseases also influence diet choice and, in one study, were present in approximately two thirds of dogs with heart disease.[5] For example, a cat with hypertrophic cardiomyopathy and a history of struvite urolithiasis would need a diet that is both sodium restricted and also nutritionally modified to reduce the risk of struvite urolith formation. Laboratory results, such as the presence of hypokalemia or hyperkalemia, also can alter diet selection.

Based on these and other patient parameters, diets can be matched to the individual patient. A number of commercial veterinary diets are specifically designed for animals with cardiac disease. The specific characteristics of these foods vary, but they are moderately to severely sodium restricted and generally have increased levels of B vitamins. Some cardiac diets may also have increased levels of taurine, carnitine, antioxidants, or n-3 fatty acids. Above all, the diet must be palatable enough that the animal eats it willingly. The authors typically determine several diets that would be appropriate for an individual animal, and these diets then are offered as choices for the owner and the pet. Having dietary choices is particularly beneficial for owners of more severely affected patients, because a cyclic or selective loss of appetite is common in these pets. All diet recommendations should include a discussion of treats, table food, and foods used for medication administration.

As mentioned earlier, anorexia is a common problem in animals with heart disease and can contribute to the syndrome of cachexia. Another important problem with anorexia is that it may affect survival by influencing an owner's decision to euthanize the pet. In one study of owners of dogs euthanized for CHF, anorexia was one of the most common contributing factors to the euthanasia decision.[8] Anorexia becomes more common as the heart disease becomes more advanced. Recommendations for managing anorexia are listed in Box 157-1.

A note of caution: For animals with an acute episode of CHF, the diet should not be changed until the patient's condition has been stabilized. Once the animal is home and has been stabilized on medications, a gradual change to a new diet can be made. Forced dietary changes when the animal is sick or starting new medications may induce food aversions.

In many cases, the desired nutrient modifications can be achieved through diet alone. However, supplementation of certain nutrients may be warranted if these nutrients are not included in a particular diet or if they are not present at high enough levels to achieve the desired effect. It is important to be aware that dietary supplements do not require proof of safety, efficacy, or quality control to be marketed. Therefore careful selection of type, dose, and brand is important to avoid toxicities or complete lack of efficacy. Recently, the United States Pharmacopeia (USP) established the Dietary Supplement Verification Program (DSVP) for human dietary supplements. Supplements with the DSVP certification mark on the label have been tested and verified by the USP for their ingredients, the finished product, and the manufacturing process. This voluntary program helps ensure the safety and quality of dietary supplements, but it does not test the overall safety of use of the product or of health claims made for it. Much additional information is needed to define the role of dietary supplements in heart disease, when they should be used, when they should not be used, and optimal dosages.

157.3.1 **Box • 157-1 Keys to Managing Anorexia in Patients with Cardiac Disease**

- Assess the patient for optimal medical control of heart failure.
- Assess the patient for side effects of medications (e.g., digoxin toxicity or azotemia).
- Feed more frequent but smaller meals.
- Warm the food to body temperature.
- Gradually introduce a more palatable diet (e.g., switch from a dry food to a canned food, change to a different brand, or have a nutritionist formulate a balanced homemade diet).
- Use flavor enhancers, such as cooked meat or fish or low-sodium tuna juice for cats, and cooked meat or sweeteners (e.g., yogurt, maple syrup, or honey) for dogs.
- Administer fish oil supplements if the diet does not contain high concentrations of omega-3 fatty acids.

In addition to finding a diet that has the desired nutritional properties and palatability, the practitioner must construct an overall dietary plan that meets the owner's expectations. This involves finding a diet that the owner perceives the pet to enjoy, providing information about acceptable treats, and devising a satisfactory method of administering medications. In one study, more than 90% of dogs with heart disease received treats, and these are often high in sodium.[5] In addition, the majority of people who administer medications to their dogs use food as a means of achieving this (Box 157-2). To ensure success with nutritional modification, it is important to include information on how best to use food for this purpose in the overall diet plan.

157.3.2 **Box • 157-2 Methods for Administering Medication to Dogs and Cats**

1. Teach the owner to pill the animal without using foods.
2. Use a Pet Piller or Pet Pill Gun (Jorgensen Laboratories, Loveland, CO).
3. Use a compounded, flavored liquid medication instead of a pill (remember that compounding may alter the pharmacokinetics of a drug).

   Caution: Always determine the sodium content of a compounded product.
4. Insert medications into appropriate foods, such as the following:
   - Fruit (e.g., grapes, banana, orange, melon)
   - Low-sodium cheese
   - Low-sodium canned pet food
   - Peanut butter (labeled as “no salt added”)
   - Home-cooked meat (without salt); not lunch meats

5. Insert medication into a Canine Veterinary Tab Pocket (Waltham, Vernon, CA)

158 CHAPTER • 158 Nutritional Management of Urinary Tract Conditions

India F. Lane

Dietary modifications can be used in managing urinary tract disease to influence excretory needs, acid-base status, fluid and electrolyte balance, and urine composition. Nutritional principles are described for acute and chronic renal failure, proteinuric renal disease, urolithiasis, and idiopathic feline lower urinary tract disease.

158.1 CHRONIC RENAL FAILURE

Chronic renal failure (CRF) is characterized by a progressive decline in renal function from renal insufficiency to azotemic renal failure to uremia to death or euthanasia.[1,2] Because diet can affect many consequences of renal failure, nutritional modification is a cornerstone of management. The most common derangements that occur with CRF include decreased ability to excrete nitrogenous wastes, phosphorus, and sodium; increased loss of potassium, and development of metabolic acidosis. Secondary hyperparathyroidism, systemic hypertension, and nonregenerative anemia are additional consequences of CRF. Dietary manipulation is designed to minimize protein precursors for urea and to minimize hyperphosphatemia and acid by-products; to provide an alkalinizing effect; and to supply adequate potassium while providing adequate calories to prevent further catabolism or malnutrition[1–3] (Table 158-1 and Chapter 260). The addition of soluble fiber to these diets has been recommended in an effort to provide fermentable substrate for bacteria in the large intestine. This may enhance both urea delivery and incorporation of ammonia generated into bacterial protein excreted in feces (nitrogen trapping).[4]

Dietary strategies also may help modulate progressive renal injury. In models of induced renal failure in dogs[5] and cats,[6] phosphorus intake has been linked to mortality, with increased mortality in animals consuming diets high in phosphorus. Phosphorus restriction appears to slow renal tubulointerstitial lesions, minimize secondary hyperparathyroidism and renal mineralization, and reduce development of hyperlipidemia.[1]

The influence of protein restriction is less clear, because an increased protein intake has not consistently hastened progression of renal failure in dogs or cats with induced renal dysfunction.[7] However, protein restriction decreases the nitrogenous solutes, phosphorus, and acid by-products that failing kidneys must handle. Protein restriction, therefore, is a feature of low-phosphorus diets designed for animals with moderate renal failure.

Modulation of dietary lipids may also be beneficial in slowing progressive renal failure. In dogs with induced renal insufficiency, supplementation of menhaden fish oil, which is high in omega 3 polyunsaturated fatty acids, resulted in reduced intraglomerular pressure, reduced proteinuria, and a slightly improved glomerular filtration rate (GFR) over a 20-week period. Dogs supplemented with safflower oil, which is high in omega 6 fatty acids, had progressive loss of renal function.[8] In another group of dogs with naturally ocurring chronic renal failure, however, the measured GFR *increased* during a 6-week period in those dogs fed safflower oil.[9]

Table • 158-1 Dietary Modifications Recommended in the Treatment of Urinary Diseases in Dogs and Cats

DISORDER	DIETARY RECOMMENDATIONS
Chronic renal failure	Reduced phosphorus
	Reduced protein
	Nonacidifying
	Potassium replete
	Reduced sodium
	Omega 3 fatty acid supplemented (dogs) +/– Increased soluble fiber
Proteinuric renal disease	Reduced protein
	Reduced sodium
	Omega 3 fatty acid supplemented (Additional modifications as above if animal is azotemic/uremic)
Struvite urolithiasis	Acidifying
	Increased moisture content (or induced diuresis)
	Reduced magnesium
	Reduced phosphorus
	Reduced protein
Calcium oxalate urolithiasis	Nonacidifying
	Reduced protein
	Adequate magnesium
	Adequate phosphorus
	Increased moisture content (or induced diuresis)
	Increased fiber (hypercalcemic cats)
Urate urolithiasis	Reduced protein (purines)
	Alkalinizing
Cystine urolithiasis	Reduced protein
	Reduced sodium
	Alkalinizing
Idiopathic lower urinary tract disease	Increased moisture
	Modifications as for struvite urolithiasis (if associated with struvite crystalluria)

Modified from Brown SA et al: Dietary considerations for urinary diseases. *In* Ettinger SJ, Feldman E (eds): *Textbook of Veterinary Internal Medicine*, 5th ed. Philadelphia, WB Saunders, p 269.

Dietary strategies may also be directed at other factors that may contribute to the progression of renal failure, including systemic hypertension, hyperparathyroidism, and renal ammoniagenesis (exacerbated by metabolic acidosis).

Studies of specific dietary components fed to dogs and cats with experimentally induced renal insufficiency have demonstrated the potential benefits of dietary modification. Recently, the overall benefit of "renal diets" has been investigated in cats and dogs with naturally occurring renal failure.[10–12] In a prospective study of cats with stable, azotemic chronic renal failure, feeding a canned renal failure diet resulted in significant reductions in plasma urea and phosphorus while prolonging survival times (median, 633 days) compared with cats that ate other diets (median, 264 days).[10] Unfortunately, diet groups were not randomized because they were determined by cat and owner preference. Consequently, cats with more advanced or complicated disease (potentially more selective about food) may have been more heavily represented in the non-renal failure diet group. Despite this limitation, the dramatic difference in survival times between the two groups supports the hypothesis regarding influence of diet on longevity.[10]

In a similar study, cats that ate low-protein/low-phosphorus diets had lower serum phosphorus concentrations and parathyroid hormone measurements than cats that ate other diets.[11] In a prospective, double-blind study of dogs with chronic renal failure, those fed a renal failure diet had delayed development of uremic crisis and a decrease in renal-related deaths as compared with dogs fed a diet formulated to mimic commercial adult maintenance diets.[12] In this study, other treatments were allowed as clinically necessary, such as phosphate-binding agents, potassium supplementation, and antihypertensive agents. Modification of the diet is recommended as soon as renal failure is detected.

158.2 ACUTE RENAL FAILURE

In acute renal failure (ARF), decline in renal function takes place over just a few days, limiting adaptability to loss of excretory function. In addition, insulin resistance, severe acidosis, release of stress hormones, and other metabolic derangements lead to a marked hypercatabolic state.[13] Optimal nutritional support in animals with ARF may minimize additional catabolism and azotemia, maximize chances for renal tissue repair, increase immunity against infectious complications, and improve survival.[13,14] Initial strategies (i.e., in the first 24 to 48 hours) are directed at managing fluid and electrolyte needs while avoiding large amounts of potentially damaging nutrients, such as amino acids or glucose. In maintenance and recovery phases after ARF, nutritional support should be provided as simple carbohydrates, fats, and protein, depending on the degree of uremia or malnutrition. Some authors recommend more protein for cats than dogs. Water-soluble vitamin supplementation is also recommended. Enteral or parenteral feeding often is required for animals with anorexia or vomiting. Aggressive, early use of antiemetics and gastrointestinal protectants is necessary to alleviate gastrointestinal erosion, hyperacidity, and reflux.[13,14]

158.3 PROTEINURIC RENAL FAILURE

A mildly to moderately reduced protein diet is recommended to limit protein loss in dogs with significant protein-losing nephropathy and normal albumin levels. If the serum albumin concentrations decrease below reference limits, protein supplementation may be necessary to improve hepatic albumin synthesis and to counter protein loss. Sodium restriction is also recommended because of the high incidence of hypertension associated with glomerular disease. In addition, omega 3 fatty acid supplementation may help modulate glomerular

inflammation and decrease systemic hypertension, as well as hyperlipidemia, hypercholesterolemia, and platelet aggregation.[15]

158.4 MINIMIZING ANOREXIA ASSOCIATED WITH RENAL DISEASE

With worsening uremia, anorexia often complicates management of renal failure and compromises quality of life.[16] First, management of uremic gastroenteritis and other metabolic consequences of renal failure alleviates uremic anorexia. Dietary changes should be made gradually in the home environment, with food introduced that has a similar texture and flavor as the historical diet. Warming food, adding water or flavored (low sodium) broths or flavoring agents (butter, cottage cheese, clam juice, and garlic), and feeding small, frequent meals may increase palatability. It is important to avoid mixing unpalatable drugs with food, force feeding, or combining feeding with stressful, unpleasant, or painful procedures, such as injections or sample collection.[16]

Originally considered for preconditioning renal transplant patients, feeding by *percutaneous* or *surgically placed gastrostomy tubes* is a valuable tool in the management of some animals with renal failure.[3,17,18] Tube access also facilitates fluid intake and administration of medications. In 56 dogs with renal failure, gastrostomy tubes were used for a mean of about 2 months, and tubes in seven dogs were used for longer than 6 months. In these 56 dogs, increased gastric bleeding (transient), peristomal infection, and inadvertent tube removal were among the reported complications.[7] Preoperative gastrostomy tube feeding support is recommended for renal transplant candidates that have lost ≥10% of their body weight.[18]

158.5 UROLITHIASIS

Dietary strategies for the prevention or dissolution of uroliths are based on the principle of urine saturation.[19,20] Crystal precipitation occurs when urine becomes *oversaturated*. The amount, concentration, and types of ions and mineral present, as well as the urine pH, determine the overall solubility of a substance. When urine is *undersaturated* with such substances in a favorable pH, crystals do not precipitate or aggregate. In fact, some crystals or uroliths dissolve in such an environment. Dietary and other management strategies for urolithiasis, therefore, are designed to create a state of undersaturation for calculogenic minerals. Undersaturation is accomplished by (1) reducing the amount of dietary urolith precursors; (2) decreasing concentration of minerals by increasing urine volume; (3) modifying the urine pH to enhance solubility; and (4) providing optimal concentrations of crystallization inhibitors.[19,20] Using these principles, diets have been formulated to aid in the dissolution of magnesium ammonium phosphate (struvite), urate, and cystine uroliths and to minimize recurrence of other urolith types (see Table 158-1 and Chapters 266 and 267).

158.6 IDIOPATHIC FELINE LOWER URINARY TRACT DISEASE (OR IDIOPATHIC CYSTITIS)

Episodic or recurrent lower urinary tract signs related to a noninfectious inflammatory disorder of unknown etiology is still a common clinical disorder of cats. Because the obstructive form of the disease was frequently associated with struvite crystalluria (and struvite crystals are still the predominant crystal found in urethral plugs), diets formulated for prevention or dissolution of struvite urolithiasis have traditionally been recommended.[21] However, many cats do not exhibit significant crystalluria along with the sterile hemorrhagic inflammation, therefore other dietary factors may be important. Dry cat food diets and decreased fluid intake appear to be significant risk factors for the development of both obstructive and nonobstructive disease, which may be reduced by maximizing moisture intake. In a prospective study of affected cats fed either a dry or canned formulation of

mineral-controlled, acidifying diet for up to 12 months, fewer recurrences and significantly reduced urine specific gravities were seen in the cats that ate the canned preparation.[22]

Cats accustomed to dry food may not accept an exclusive canned food diet. Therefore other methods of increasing water intake must be considered, such as adding water to existing food; placing fresh, full water bowls near food; adding broths or juices to food or water; offering distilled or bottled water; leaving a faucet dripping slowly, or using pet water "fountains." Constancy of diet (i.e., limiting diet changes) also has been proposed as a protective measure in the management of idiopathic cystitis in cats.[23]

159 CHAPTER • 159 Parenteral Nutritional Support

Daniel Chan

Metabolic responses to illness or injury place critically ill animals at high risk for malnutrition and its deleterious effects. These problems include alterations in energy metabolism, compromised immune function, decreased wound healing, and, probably a negative impact on overall survival.[1–3] Whereas healthy animals lose primarily fat when they do not receive adequate calories (simple starvation), sick or traumatized patients catabolize lean body mass when they are not provided with sufficient calories (stressed starvation). Inadequate calorie intake is a common problem in critically ill animals due to anorexia, an inability to eat or tolerate feedings (e.g., vomiting), or decreased absorptive capabilities.[1,4]

Because malnutrition may occur quickly in these animals, it is important to provide nutritional support by either enteral or parenteral means if oral intake is not adequate. The goals of nutritional support are to prevent development of malnutrition and to treat malnutrition when present. Although unproven in dogs and cats, treatment or prevention of malnutrition is thought to decrease morbidity and mortality.[1,2,5–7] Whenever possible, nutritional support via the enteral route should be used because it is the safest, most convenient, most physiologically sound, and least expensive method. Although enteral nutrition is preferred in critically ill animals, parenteral nutrition (PN) is an established method of providing nutritional support to dogs and cats whose gastrointestinal tracts cannot tolerate enteral feedings.[3,5–6,8–9]

Although the use of parenteral nutritional support has certainly increased in recent years, there sometimes is a perception that this technique is technically difficult, associated with many complications, and limited to university hospitals and referral centers. In reality, parenteral nutritional support can be adopted in many practices and complications can be significantly reduced with proper management techniques. The goals of this chapter are to outline identification of dogs and cats most likely to benefit from PN; to review the process of formulating, implementing, and monitoring parenteral nutritional support; and to discuss how PN can be incorporated into various practice situations.

159.1 NUTRITIONAL ASSESSMENT

The first step in consideration of nutritional support is appropriate assessment. Assessing nutritional status via objective measurements of body composition (e.g., anthropometry, bioelectrical impedance, dual energy X-ray absorptiometry, or serum indicators of malnutrition) is rarely employed in clinical veterinary medicine. Therefore subjective clinical assessment remains paramount in identification of malnourished animals that require nutritional support as well as those in which nutritional support will help prevent malnutrition. Indicators of malnutrition include weight loss, poor hair coat, muscle wasting, signs of inadequate wound healing, hypoalbuminemia, lymphopenia, and coagulopathy. However, these abnormalities are not specific to malnutrition and do not occur early in the process. In addition, fluid shifts may mask weight loss in critically ill animals. Given these limitations, it is crucial to identify early risk factors that may predispose patients to malnutrition, such as anorexia of greater than 3 days' duration, serious underlying disease (e.g., trauma, sepsis, peritonitis, pancreatitis, gastrointestinal surgery), or significant protein loss (e.g., protracted vomiting, diarrhea, protein-losing nephropathies, draining wounds, or burns).

Nutritional assessment also identifies factors that can affect the nutritional plan, such as the identification of specific electrolyte abnormalities; hyperglycemia, hypertriglyceridemia, or hyperammonemia; or comorbid

illnesses, such as renal or hepatic disease. Such findings require adjustments to be made to the formulation of PN and in some cases prompt changing the nutritional plan. Appropriate laboratory analyses (e.g., serum biochemical profile, serum ammonia, urinalysis) should be performed in all dogs and cats to assess these parameters.

159.2 GOALS OF NUTRITIONAL SUPPORT

The goals of nutritional support are to provide for the animal's ongoing nutritional needs, prevent or correct nutritional deficiencies and imbalances, minimize metabolic derangements, and prevent further catabolism of lean body tissues. Restoration of optimal body condition is not necessarily the goal of nutritional support in the acute stages of disease. In severely malnourished dogs and cats, nutritional support should be directed to preservation of lean body tissue and organ function, rather than complete reversal of malnutrition, which is accomplished only when the animal becomes convalescent. The necessity for instituting nutritional support is dictated by individual needs and not by the specific disease. The ultimate goal of nutritional support is to provide the necessary nutrients and calories until the dog or cat voluntarily consumes an adequate amount of food in its own environment.

159.3 NUTRITIONAL PLAN

The key to successful nutritional management of a critically ill animal lies in proper diagnosis and treatment of underlying disease. Another crucial factor is selection of the appropriate route for nutritional support. Providing nutrition via a functional digestive system is the preferred route of feeding and so particular care should be taken to determine whether enteral feedings would be tolerated. Even if only small amounts of enteral nutrition would be tolerated, this route of feeding should be pursued and supplemented with PN as necessary to meet nutritional needs. On the basis of the nutritional assessment, the anticipated duration of nutritional support, and appropriate route of delivery (i.e., enteral or parenteral) a nutritional plan is formulated to meet each dog's or cat's nutritional needs.

The first steps in instituting nutritional support include re-establishing proper hydration status, correction of electrolyte or acid-base disturbances, and achieving hemodynamic stability. Commencing nutritional support before these abnormalities are addressed can increase risk of complications and, in some cases, further compromise the animal. Implementation of the nutritional plan should be gradual, with the goal of reaching target level of nutrient delivery in 48 to 72 hours.

159.4 CALCULATION OF NUTRITIONAL REQUIREMENTS

Ideally, the provision of nutritional support should provide ample substrates for gluconeogenesis, protein synthesis, and energy necessary to maintain homeostasis. The clinician must ensure that enough calories are being provided to sustain critical physiologic processes, such as immune function, wound repair, and cell division and growth. Therefore calculating the pet's total energy expenditure is necessary. However, as direct measurements of energy expenditure in clinical dogs and cats are still in the developmental phases, the use of mathematical formulas remains the only practical means of estimating energy requirement. The resting energy requirement (RER) is defined as the number of calories required for maintaining homeostasis at rest in a thermoneutral environment while the animal is in a postabsorptive state.[10] Although there are several formulas proposed to calculate the RER, a widely used allometric formula can be applied to both dogs and cats of all weights. For animals that weigh between 2 and 30 kg, there is also a linear formula that provides reasonable estimation of the RER.

$$\text{RER} = 70 \times (\text{current body weight in kg})^{0.75}$$

or for animals weighing between 2 and 30 kg:

$$\text{RER} = (30 \times \text{current body weight in kg}) + 70$$

Despite the convention of multiplying the RER by an illness factor between 1.0 to 1.5 to account for increases in metabolism associated with different diseases and injuries, less emphasis is now being placed on such subjective and extrapolated factors.[4] The current recommendation is to use more conservative energy estimates, that is, to start with the animal's RER, to avoid overfeeding. Overfeeding can result in metabolic and gastrointestinal complications, hepatic dysfunction, and increased carbon dioxide production.[9]

As the preservation of lean body mass is a primary goal of nutritional support, close monitoring of body weight, fluid distribution, response or tolerance to feedings, and changes in the underlying condition should dictate whether to increase the number of calories provided in the nutritional plan. Typically, if an animal continues to lose weight on nutritional support, the number of calories provided should be increased by 25% and the plan should be reassessed in a few days. Additional adjustments to the nutritional plan might also include the addition or restriction of electrolytes such as magnesium and potassium as dictated by serial biochemical profiles.

159.5 NUTRITIONAL SUPPORT

A major advantage of enteral nutrition is superior maintenance of intestinal structure and function, as the presence of nutrients within the intestinal lumen elicits trophic effects that mediate mucosal cell proliferation. It has also been proposed that a lack of enteral nutrition contributes to the impairment of mucosal barrier function, which allows for the translocation of intestinal bacteria or endotoxins leading to sepsis and a systemic inflammatory response.

However, in patients that are unable to tolerate enteral feedings, such as those that are vomiting, regurgitating, or unable to protect their airway, parenteral nutrition should be considered. Inability to tolerate enteral feeding is, in fact, the only major indication for parenteral nutritional support. Although obtaining enteral access in critically ill animals can be difficult, every effort must be made to ensure that a functional gastrointestinal tract is not bypassed. A more extensive review of enteral nutrition is provided elsewhere (see Nasoesophageal, Esophagostomy, and Gastrostomy Tube Placement Techniques).

159.6 PARENTERAL NUTRITION

Parenteral nutrition has sometimes been characterized as a technique fraught with complications. In reality, many of the complications attributed to PN in the past might have had more to do with overfeeding or "hyperalimentation," rather than with the route of feeding itself. Although metabolic complications can be associated with PN, these complications are generally mild, have minimal consequences, and rarely require discontinuation of nutritional support. Septic complications associated with PN can be dramatically minimized with careful attention to aseptic technique in the compounding of PN, placement of dedicated PN catheters, and monitoring of the catheter site.

159.7 TYPES OF PARENTERAL NUTRITION

Given that the different types of PN can be defined in a number of ways, it may be simpler to categorize the different types of parenteral nutrition in terms of calories provided, that is, when parenteral nutrition is formulated to meet 100% of an animal's energy requirements, it is referred to as *total parenteral nutrition* (TPN). Parenteral

nutrition formulated to provide only a portion of the energy requirements, typically 40% to 70%, is termed *partial parenteral nutrition* (PPN). The lower osmolarity of PPN solutions, as compared with TPN solutions, is achieved by diluting the solution (ideally to less than 800 mOsm/L), which decreases the caloric and protein density but makes it suitable for administration via peripheral veins. For this reason, PPN may also be referred to as *peripheral parenteral nutrition.* The lower osmolarity is achieved in part, by utilizing 5% dextrose instead of 50% dextrose in the preparation of PPN and sometimes by the addition of isotonic and sometimes hypotonic crystalloids. As such, PPN is intended for short-term use (less than 5 days) and should be limited to dogs and cats that are not debilitated. Partial parenteral nutrition is also sometimes used as interim nutritional support until TPN can be formulated or it is used when specific contraindications exist to placement of jugular catheters, such as increased intracranial pressure or coagulopathies.

159.8 PARENTERAL NUTRITION COMPONENTS

Parenteral nutrition is formulated as a mixture of a carbohydrate source (dextrose), amino acids, and, usually, a fat source (lipid). Carbohydrates in the form of dextrose (typically 5% or 50%), may have benefits beyond acting as a fuel substrate. These potential benefits include stimulation of insulin secretion, reduction of muscle protein catabolism, and inhibition of hepatic glucose output, which may spare muscle proteins from being catabolized for gluconeogenesis. However, the sole administration of dextrose or supplementation of maintenance fluids with dextrose, in most cases, does not amount to adequate nutritional support and should therefore be discouraged. For example, a 5% dextrose infusion provides only 170 kcal per liter of solution and would provide less than 25% of the RER, at maintenance fluid rates. Dextrose infusions are more appropriate for the treatment of hypoglycemia rather than nutritional support.

Crystalline amino acids solutions are an essential component of PN. The importance of supplying amino acids relates to the maintenance of positive nitrogen balance and repletion of lean body tissue, which may be vital in the recovery of critically ill dogs and cats. Supplementation of amino acids may support protein synthesis and spare tissue proteins from being catabolized via gluconeogenesis.[9] The most commonly used amino acid solutions (Travasol, Clintec Nutrition, Deerfield, IL) contain most of the essential amino acids for dogs and cats, with the exception of taurine. However, as PN is typically not used beyond 10 days, the lack of taurine does not become a problem in most circumstances. Amino acid solutions are available in different concentrations from 4% to 10%, but the most commonly used concentration is 8.5%. Amino acid solutions are also available with and without electrolytes. Animals with normal serum electrolytes typically receive amino acid solutions with electrolytes, whereas those with electrolyte disturbances may benefit from amino acid solutions without electrolytes. Special formulations of amino acid solutions containing higher concentrations of the branched-chain amino acids are available at a much greater expense. Although these solutions were originally thought to be useful in management of highly catabolic metabolic diseases or when hepatic encephalopathy was present, studies have not confirmed a clear benefit in overall survival.[12]

Lipid emulsions are the calorically dense component of PN and a source of essential fatty acids. Lipid emulsions are isotonic and are available in 10% to 20% solutions (Intralipid, Clintec Nutrition, Deerfield, IL). These commercially available lipid emulsions are made primarily of soybean and safflower oil and provide predominantly long-chain polyunsaturated fatty acids, including linoleic, oleic, palmitic, and stearic acids. These solutions are emulsified with egg yolk phospholipids and their tonicity is adjusted with glycerol. The emulsified fat particles are comparable in size to chylomicrons and are removed from the circulation via the action of peripheral lipoprotein lipase. A common misconception exists in regard to the use of lipids in cases of pancreatitis. Although hypertriglyceridemia may be risk factor for pancreatitis, infusions of lipids have not been shown to increase pancreatic secretion or worsen pancreatitis and are therefore considered safe.[13] One exception, however, could be when serum triglycerides are increased, which indicates a clear failure of triglyceride clearance.

According to the most recent guidelines provided by the American Society of Parenteral and Enteral Nutrition, humans with serum triglycerides exceeding 400 mg/dL should have the lipid proportion in PN markedly reduced or eliminated altogether.[13] Although specific data regarding the maximal safe level of lipid administration in dogs and cats is not available, it would seem prudent to maintain normal serum triglyceride concentrations.

Another concern surrounding the use of lipids in PN are purported immunosuppressive effects via impairment of the reticuloendothelial system, particularly in PN solutions containing a high percentage of lipid.[9] Despite *in vitro* evidence supporting the notion that lipid infusions can also suppress neutrophil and lymphocyte function, studies have not yet correlated lipid use and increased rates of infectious complications.

Daily vitamin recommendations for dogs and cats that receive PN are extrapolated from established oral nutritional requirements.[9] Multivitamin preparations intended for intravenous administration provide a convenient and practical means for vitamin supplementation. It is recommended to add 0.2 ml/kg of a multivitamin preparation (M.V.I.-12 NeoSan Pharmaceuticals Inc., Wilmington, NC) to each PN bag at the time of compounding, up to 10 mL/day. This provides most of the water-and fat-soluble vitamins, except for vitamin K. In certain situations (e.g., longstanding malnutrition, malabsorptive disorders), 0.5 mg/kg of vitamin K can be administered subcutaneously, once weekly. Trace metals (4 Trace Elements, Abbott Laboratories, North Chicago, IL) can also be added to the PN solution at a dose of 0.1 mL/kg (up to 5 mL/day) to provide zinc, manganese, copper, and chromium. Although vitamins are commonly added to PN solutions, trace metals are usually only added when PN is to be administered for greater than 5 days or when food has not been consumed for a prolonged period.

The addition of other parenteral medications to the PN admixture is possible; however, their compatibility must first be verified. Drugs that are known to be compatible and sometimes added to PN include heparin, insulin, potassium chloride, and metoclopramide. Although the addition of insulin to PN is often required in people receiving PN, the hyperglycemia seen in dogs and cats receiving PN does not usually require insulin administration; however, diabetic patients will require adjustments to their insulin regimen. Although there is a described veterinary protocol for the addition of insulin directly to PN, it is often easiest to manage diabetics on PN with subcutaneous injections of insulin.[9] The addition of metoclopramide to PN solutions is often useful in the management of vomiting and ileus, which are commonly encountered in critically ill animals.

589

159.9 PARENTERAL NUTRITION COMPOUNDING

Based on the nutritional assessment and plan, PN can be formulated according to the worksheets found in Boxes 159-1 and 159-2. For TPN (see Table 159-1), the first step is the calculation of the animal's RER. Protein requirements (grams of protein required per day) are then calculated, taking into consideration factors such as excessive protein losses or severe hepatic or renal disease. Although some recommendations provide all energy requirements with only dextrose and lipids, the protocol listed accounts for the energy provided from amino acids in the calculation and subtract it from the daily RER to estimate the total non-protein calories required. The non-protein calories are then usually provided as a 50:50 mixture of lipids and dextrose; however, this ratio can be adjusted in cases of persistent hyperglycemia or hypertriglyceridemia (e.g., a higher proportion of calories would be given from lipid in an animal with hyperglycemia). The calories provided from each component (amino acids, lipids, and dextrose) are then divided by their respective caloric densities and the exact amounts of each component are added to the PN bags in an aseptic fashion. The amount of TPN delivered will often provide less than the daily fluid requirement. Additional fluids can either be added to the PN bag at the time of compounding or be provided as a separate infusion.

159.9.1 Box • 159-1 Total Parenteral Nutrition (TPN) Calculations

1. Calculate resting energy requirement (RER)

RER =70 × (current body weight in kg)$^{0.75}$ or for animals weighing between 2 and 30 kg:

RER = (30 × current body weight in kg) +70 — RER =___kcal/day

2. Protein requirements

	Canine (gm/100 kcal)	Feline (gm/100 kcal)
*Standard	4	6
*Reduced (hepatic/renal disease)	2-3	3-4
*Increased (excessive protein losses)	6	6

$(RER \div 100) \times \underset{\text{protein req}}{____} \text{ gm/100 kcal} = ____ \text{ gm protein required/day}$

3. Volume of nutrient solutions required

a. 8.5% amino acid solution = 0.085 gm protein/ml

___g protein required/day ÷ 0.085 gm/ml — =___ ml/day of amino acids

b. Non-protein calories:

The calories supplied by protein (4 kcal/gram) are subtracted from the RER to get total non-protein calories needed.

___g protein req/day × 4 kcal/gram — =___kcals provided by protein

RER – kcals provided by protein — =___total non-protein kcal/day required

c. Non-protein calories are usually provided as a 50:50 mixture of lipid and dextrose

*20% lipid solution = 2 kcal/ml

To supply 50% of non-protein calories

___lipid kcal required ÷ 2 kcal/ml — =___mls of lipid

*50% of dextrose solution = 1.7 kcal/ml

To supply 50% of non-protein calories

___dextrose kcal required ÷ 1.7 kcal/ml — =___mls of dextrose

4. Total daily requirements

___mls of 8.5% amino acid solution

___mls of 20% lipid

___mls of 50% dextrose

___total mls of TPN solution to be administered over 24 hr

Note: Using a common 8.5% amino acid solution containing potassium (i.e., Travasol), TPN made according to this worksheet will provide potassium at higher than maintenance levels. Therefore you may not need to supplement potassium in any other fluids your patient is receiving. TPN for animals that are hyperkalemic should be formulated using amino acid solutions without electrolytes. Rates of other IV fluids being concurrently administered should be adjusted accordingly.

For formulation of PPN, Box 159-2 provides a step-by-step protocol in which animals of various sizes can be given 70% of their RER and approximately meet their daily maintenance fluid requirement. In very small animals (≤3 kg), the amount of PPN will exceed the maintenance fluid requirement and increase the risk for fluid overload, so adjustments in volume are necessary. Also, in animals requiring conservative fluid administration (e.g., congestive heart failure), these calculations for PPN may provide more fluid then would be safe. This formulation has been designed so that the proportion of each PN component is dependent on animal weight such that a smaller animal (between 3 and 5 kg) will receive proportionally more calories from lipids, compared to a large dog (greater than 30 kg), which would receive more calories in the form of carbohydrates. This allows the resulting formulation to approximate the daily fluid requirement.

Ideally, compounding of parenteral nutrition should be done aseptically under a laminar flow hood using a semi-automated, closed-system, parenteral nutrition compounder (e.g., Automix compounder, Clintec Nutrition, Deerfield, IL). If an automated compounder is not available, manual compounding can be done in a clean, low-traffic area with strict adherence to aseptic technique using a 3-in-1 bag (All-In-One EVA container, Clintec Nutrition, Deerfield, IL). Given these ideal conditions, it is often easier and more cost effective to have a local human hospital or a human home healthcare company compound parenteral nutrition solutions. Alternatively, commercial ready-to-use preparations of glucose or glycerol and amino acids are available for intravenous (peripheral) use (Table 159-1). Although these ready-to-use preparations are convenient, they provide only 30% to 50% of caloric requirements when administered at maintenance fluid rates and as a result should only be used for interim nutritional support or to supplement low-dose enteral feedings.

159.9.2

Box • 159-2 Partial Parenteral Nutrition (PPN) Calculations

1. Calculate resting energy requirement (RER)

RER =____ kcal/day

RER = 70 × (current body weight in kg)$^{0.75}$ or for animals weighing between 2 and 30 kg:

RER = (30 × current body weight in kg) + 70

2. Calculate the partial energy requirement (PER):

Plan to supply 70% of the animal's RER with PPN: PER = RER × 0.70 =____ kcal/day

3. Proportion of nutrient requirements according to body weight:

(Note for animals ≤3 kg, the formulation will exceed maintenance fluid requirements)

a. Cats and dogs 3 to 5 kg:

PER × 0.20 =____ kcals/day carbohydrate required

PER × 0.20 =____ kcals/day protein required

PER × 0.60 =____ kcals/day lipid required

b. Cats and dogs 6 to 10 kg:

PER × 0.25 =____ kcals/day carbohydrate required

PER × 0.25 =____ kcals/day protein required

PER × 0.50 =____ kcals/day lipid required

c. Dogs 11 to 30 kg:

PER × 0.33 =____ kcals/day carbohydrate required

PER × 0.33 =____ kcals/day protein required

PER × 0.33 =____ kcals/day lipids required

d. Dogs >30 kg:

PER × 0.50 =____ kcals/day carbohydrate required

PER × 0.25 =____ kcals/day protein required

PER × 0.25 =____ kcals/day lipid required

4. Volumes of nutrient solutions required:

a. 5% dextrose solution = 0.17 kcals/ml =____ ml/day dextrose

____kcals carbohydrate required/day ÷ 0.17 kcals/ml

b. 8.5% amino acid solution = 0.34 kcals/ml

=____ ml/day amino acids

____kcals protein required/day ÷ 0.34 kcals/ml

c. 20% lipid solution = 2 kcal/ml

=____ ml/day lipid

____kcals lipid required/day ÷ 2 kcals/ml

=____ total ml of PPN to be administered over 24 hrs

Note: This formulation provides approximately a maintenance fluid rate. Commonly used 8.5% amino acid solutions (i.e., Travasol) with electrolytes contain potassium. For animals ≤35 kg, the PPN solution made according to this worksheet will provide approximately maintenance levels of potassium. For animals >35 kg, the potassium contained in the PPN solution will be lower than maintenance levels. Rates of other IV fluids being concurrently administered should be adjusted accordingly.

159.10 PARENTERAL NUTRITION ADMINISTRATION

The administration of any PN requires a dedicated catheter used solely for PN administration and that is placed using aseptic technique. In most cases, this will require placement of additional catheters because PN should not be administered through existing catheters that were placed for reasons other than PN. Long catheters composed of silicone, polyurethane, or tetrafluroethylene are recommended for use with any type of PN to reduce the risk of thrombophlebitis. [3–4] Multilumen catheters are often recommended for TPN because they can remain in place for long periods and can also be used for blood sampling and administration of additional fluids and intravenous medications without the need for separate catheters placed at other sites. [5,11]

590 591

Table • 159-1 Commercially Available Alternatives for Partial Parenteral Nutrition (PPN)

PRODUCT NAME	FEATURES	MANUFACTURER
Clinimix	2.75% amino acid 5% dextrose	Clintec Nutrition, Deerfield, IL
Quickmix	2.75% amino acid 5% dextrose	Clintec Nutrition, Deerfield, IL
ProcalAmine	3% amino acids 3% glycerol	McGraw Inc., Irvine, CA

Note: These solutions only provide 30% to 50% of resting energy requirements when administered at maintenance fluid rates. Therefore these should only be used as an interim form of nutritional support or to supplement low-dose enteral nutrition.

Although placement of multi-lumen catheters does require more technical skills than conventional jugular catheters, they can be valuable in treatment of any critically ill pet. The high osmolarity of TPN solutions (often 1200 mOsm/L) require its administration through a central venous (jugular) catheter, whereas PPN solutions can be administered through either a jugular catheter or catheters placed in peripheral veins. The concern with administering fluids high in osmolarity is that it may increase the incidence of thrombophlebitis, although this has not been consistently demonstrated in veterinary medicine.

Because of the various metabolic derangements associated with critical illness, TPN should be instituted gradually over 48 hours. At the hospital where the author practices, TPN is started typically at 50% of the RER on the first day and then increased to the targeted amount by the second day. In most cases, PPN can be started without gradual increase. It is also important to adjust the rates of other fluids being concurrently administered. For both TPN and PPN, the animal's catheter and infusion lines must be handled aseptically at all times to reduce the risk of PN-related infections.

Parenteral nutrition should be administered as continuous rate infusions over 24 hours via fluid infusion pumps. Inadvertent delivery of massive amounts of PN can result if administration is not properly regulated. Cyclic administration of PN (i.e., alternating PN with other parenteral fluids every 12 hr) has also been described. However, this practice is not recommended as it circumvents maintenance of a closed-system for PN

administration and can increase the rate of complications. Once a bag of PN is set up for administration, it should not be disconnected even for walks or diagnostic procedures. The drip regulator is decreased to a slow drip and accompanies the pet throughout the hospital. Administration of PN through an in-line filter (Air eliminating filter, Clintec Nutrition Division, Deerfield, IL) is also recommended and is attached at the time of set up. This set-up process is performed daily with each new bag of PN. Each bag should only hold one day's worth of PN and the accompanying fluid administration sets and in-line filter are changed at the same time using aseptic technique. Discontinuation of PN should be done when the animal resumes consuming an adequate amount of calories of at least 50% of RER. Whereas TPN should be gradually discontinued over a 6-to 12-hour period, PPN can be discontinued abruptly.

159.11 COMPLICATIONS

As with any therapy for critically ill animals, complications can occur. Complications associated with PN can include mechanical complications of the catheter and lines, thrombophlebitis, metabolic abnormalities, and sepsis. Mechanical complications such as inadvertent catheter removal, catheter occlusion, and line disconnection or breakage are probably not inherently related to PN and are likely no more common than in any dog or cat with an intravenous catheter. Metabolic complications are much more likely to be related to PN and include hyperglycemia, hypertriglyceridemia, hyperbilirbinemia, increased alkaline phosphatase activity, azotemia, electrolyte shifts, and hyperammonemia.[2,5,11] The more commonly encountered complications, namely hyperglycemia and hypertriglyceridemia, are for the most part transient and can be effectively managed without serious consequences. Decreasing the rate of infusion for 12 to 24 hours is often effective; although in some instances, re-formulation of PN is required. Animals with biochemical changes subsequent to initiation of PN should have more frequent evaluation of laboratory parameters.

Septic complications, including cathetersite infections with and without systemic sepsis have also been reported in dogs and cats receiving PN but are uncommon and range from 3% to 12% in dogs and cats that receive PN.[5,11] Septic complications can be minimized by strict adherence to established protocols and careful attention to early signs of problems relating to catheter care. Any catheter suspected of causing fever, white cell count elevations, or other sign compatible with infection should be removed and cultured.

One of the proposed advantages of PPN over TPN is lower risk of complications. This is supported by a recent study that documents lower rates of complications in dogs and cats receiving PPN, compared with previously reported complication rates associated with TPN in dogs.[5,11] Although direct comparisons between the two patient populations cannot be made, there were approximately 0.17 complications per day of PPN administration versus 0.53 complications per day reported with TPN administration in dogs.[5,11] Reasons for these differences could be attributed to differences in severity of illness between these animal populations, although there is a potential that hypocaloric nutritional support may actually confer some benefits in certain populations, including lower complication rates.[15]

159.12 MONITORING

Given the potential for complications, monitoring of dogs and cats receiving PN is a vital part of nutritional support. This monitoring is similar to that already in place for critically ill pets. Careful monitoring of the catheter site is recommended to detect problems early (e.g., signs of inflammation or malposition) and should be done on a daily basis. The catheter should be evaluated for patency and the bandage should be changed daily. At a minimum, body weight, body temperature, respiratory rate, catheter site, and serum glucose should be evaluated daily. All blood tubes should be inspected for visible lipemia. Monitoring of other parameters (e.g., electrolytes, complete

blood count, biochemical profile) may also be indicated. Persistent hyperglycemia, hypertriglyceridemia, or signs of encephalopathy should prompt re-evaluation and may necessitate decreasing rate of infusion or re-formulation of parenteral nutrition and serial evaluation of blood work.

159.13 SUMMARY

With the growing recognition that nutritional support is an integral part of the therapeutic regimen for many critically ill pets, it is becoming increasingly important for veterinarians to be able to incorporate parenteral nutritional support in their practice or to refer these pets to facilities capable of providing such therapy when necessary. Proper identification of dogs and cats most likely to benefit from PN and the ability to formulate, administer, and monitor PN are key factors in ensuring successful incorporation of parenteral nutritional support in their care.

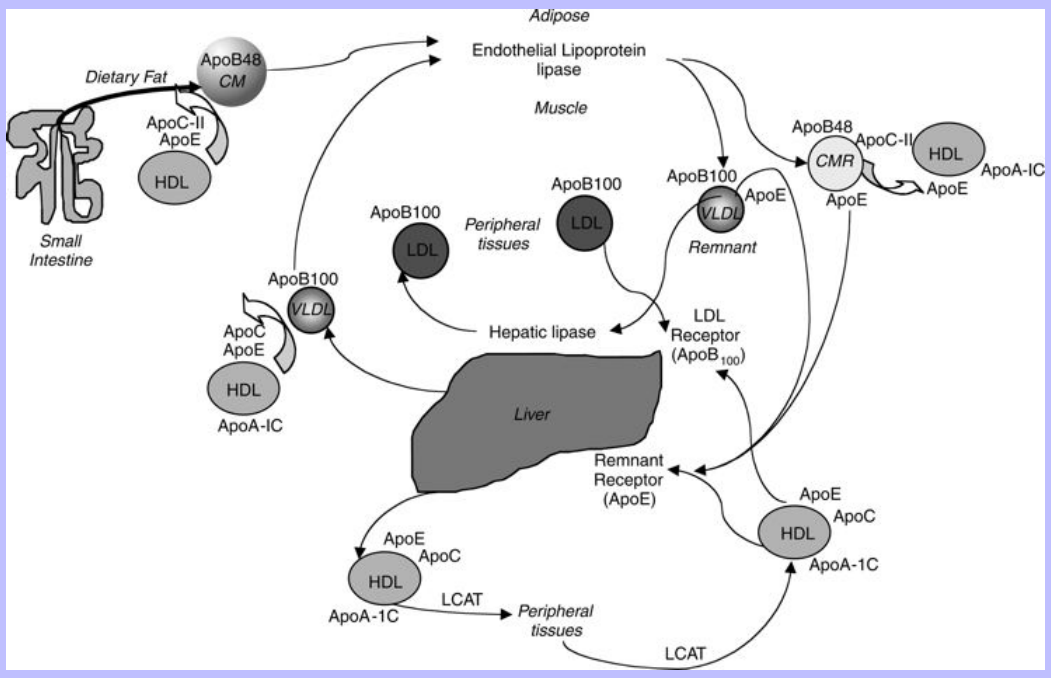
160 CHAPTER • 160 Dietary and Medical Considerations in Hyperlipidemia

Denise A. Elliott

Hyperlipidemia is a consequence of elevated plasma concentrations of triglyceride and/or cholesterol and is due to a disturbance in plasma lipoprotein metabolism.[1] In the fasted state hyperlipidemia is an abnormal finding that represents either accelerated production or delayed degradation of lipoproteins. The lipoproteins function to transport insoluble triglyceride and cholesterol through the blood. Lipoproteins consist of a triglyceride and cholesteryl ester core surrounded by a surface layer of cholesterol, phospholipid, and apolipoproteins. The apolipoproteins (A, B, C, E) are responsible for the structure of the lipoprotein particle, for binding of the particle to cell surface receptors, and activation of enzymes.[1] There are four major classes of lipoproteins that differ in their lipid and apoprotein content and their physicochemical characteristics. These variabilities include size, density, and electrophoretic mobility.

Lipoproteins are categorized according to their buoyant density upon ultracentrifugation into the chylomicron, very–low-density lipoprotein (VLDL), low-density lipoprotein (LDL), and the high-density lipoprotein (HDL). The classification system is arbitrary and it should be appreciated that there is significant structural and functional heterogeneity within each category. In addition, the system is dynamic; one class produces another during its metabolism (Figure 160-1). The chylomicron and VLDL are involved primarily in triglyceride metabolism, whereas HDL and LDL are involved primarily in cholesterol metabolism.

Figure 160-1 Schematic representation of lipid metabolism. *CM,* Chylomicron; *CMR,* chylomicron remnant; *VLDL,* very low-density lipoprotein; *LDL,* low-density lipoprotein; *HDL,* high-density lipoprotein; *LCAT,* lecithin: cholesterol acyl transferase.



160.1 PATHOPHYSIOLOGY

After digestion and absorption, cholesterol and triglyceride are packaged into chylomicron particles by enterocytes. Chylomicrons are secreted into mesenteric lymph, through which they ultimately reach the systemic circulation. Here they receive Apo E and Apo C-II from HDL. In adipose and muscle tissues, endothelial lipoprotein lipase is activated by apoprotein C-II and hydrolyzes the triglyceride core of the chylomicron to free fatty acids and glycerol. The free fatty acids diffuse into adjacent tissues and are either resynthesized into triglyceride and stored (adipocyte) or used for energy (myocyte). Lipoprotein lipase activity is influenced by factors such as heparin, insulin, glucagon, and thyroid hormone. Depletion of the triglyceride component of the chylomicron alters the surface so that the chylomicron is converted into a chylomicron remnant. The remnant particle transfers phospholipid and Apo C-II back to the HDL particle, prior to being recognized and removed from the circulation by specific Apo-E hepatic remnant receptors. Within the hepatocyte, the contents of the chylomicron remnant are degraded and utilized. Chylomicrons are present in plasma 30 minutes to 2 hours after a fat-containing meal and hydrolysis is normally complete within 6 to 10 hours after a meal.

592
593

Intrahepatic free fatty acids may originate from residual dietary triglyceride present in chylomicron remnant particles, from endogenous production secondary to surplus dietary carbohydrate, and from excessive endogenous mobilization. Intracellular hormone sensitive lipase is responsible for hydrolysis of stored adipocyte triglyceride to release free fatty acids and glycerol. Hormone sensitive lipase can be activated by epinephrine, norepinephrine, ACTH, corticosteroids, growth hormone, thyroid hormone, and insulin deficiency. Excess free fatty acids that are not directly oxidized for energy are transformed by the hepatocyte into triglyceride, packaged into VLDL particles, and secreted into blood. Analogous to chylomicron metabolism, the VLDL particle acquires ApoC-II and ApoE from the VLDL particle. Endothelial lipoprotein lipase then removes and hydrolyzes the triglyceride portion of the VLDL into free fatty acids and glycerol. In addition, an endothelial hepatic lipase will also hydrolyze the triglyceride portion of the VLDL. Removal of the triglyceride core converts the VLDL to a LDL particle. The LDL particle is a cholesterol-and phospholipid-rich entity that functions to transport cholesterol to tissues where it may be used for membrane synthesis or steroid hormone production. Ultimately, the LDL particle binds to the LDL receptor that recognizes $ApoB_{100}$, and is removed by the liver.

The liver also secretes nascent HDL particles into the circulation. These particles consist of a phospholipid bilayer, unesterified cholesterol, Apo C, Apo E, and Apo-A-I. The HDL acts as a reservoir of Apo C and Apo E and transfers these apolipoproteins to chylomicron and VLDL particles. Plasma lecithin: cholesterol acyl transferase (LCAT), activated by Apo-A-I, esterifies cholesterol to hydophobic cholesteryl ester, which moves from the surface to the inner core of the HDL. A concentration gradient is thus produced such that excess tissue cholesterol is transferred to the HDL particle. HDLs scavenge excess unesterified cholesterol from cells and other lipoproteins and return it to the liver for excretion into bile. This process is often referred to as *reverse cholesterol transport*. In humans, a second enzyme (cholesteryl ester transfer protein; CETP) can function to transfer HDL cholesteryl esters to chylomicrons, VLDL and LDL particles, in exchange for triglyceride. However, dogs do not appear to have CETP. Rather, the HDL particles are removed by the liver via Apo E binding LDL and remnant-receptors.[2] It is not yet apparent if the cat has CETP.

Hypertriglyceridemia can develop secondary to increased chylomicron production (excessive dietary intake of lipid), ineffective clearance of the chylomicron particle, increased VLDL production (excessive dietary intake of lipids and/or carbohydrate, excessive endogenous production, or mobilization of lipids), and ineffective clearance of the VLDL particle. Likewise, hypercholesterolemia can arise from increased production of the LDL precursor (VLDL), or reduced clearance of the LDL or HDL particle.

160.2 CLASSIFICATION

Post-prandial hyperlipidemia is the most common cause of hyperlipidemia in the dog and cat. This is a normal physiologic manifestation caused by the production of triglyceride-rich chylomicrons and usually resolves within 2 to 10 hours. Pathologic abnormalities in plasma lipids and lipoproteins may be of genetic or familial origin (primary) or arise as a consequence of disease (secondary). Primary hypertriglyceridemias include idiopathic hyperlipidemias of miniature Schnauzers and hyperchylomicronemia of cats. Idiopathic hyperlipidemia of miniature Schnauzers is characterized by excessive VLDL particles with or without concurrent chylomicronemia, and mild hypercholesterolemia.[3] The exact mechanism and genetics have not been fully elucidated. Feline familial hyperlipidemia is characterized as a fasting chylomicronemia with a slight increase in VLDL and is due to production of an inactive lipoprotein lipase.[4] Idiopathic hyperchylomicronemia has also been observed in dogs and is characterized by hypertriglyceridemia, hyperchylomicronemia, and normal serum cholesterol concentrations. Idiopathic hypercholesterolemia due to an increase in LDL has been reported in Doberman Pinschers and Rottweilers.

Diseases associated with secondary hyperlipidemia include endocrine disorders (hypothyroidism, diabetes mellitus, hyperadrenocorticism), nephrotic syndrome, cholestasis, and drug-induced (glucocorticoids, megastrol acetate).[5] Hypothyroidism is the most common cause of hypercholesterolemia in the dog. It is attributed to both a decrease in lipid synthesis and degradation (lipid degradation is more severely affected). Decreased lipoprotein lipase activity contributes to the impaired removal of triglyceride-rich lipoproteins. In addition, thyroid hormone deficiency reduces the biliary excretion of cholesterol. The resultant increase in intrahepatic cholesterol down-regulates the hepatic LDL receptor, increasing the level of circulating LDL and HDL. Insulin deficiency reduces the production of lipoprotein lipase, with subsequent decreased clearance of triglyceride-rich lipoproteins. Furthermore, hormone sensitive lipase is activated, which causes the release of large quantities of free fatty acids into the blood, which are ultimately converted by the liver into triglycerides, packaged into VLDL particles, and secreted back into the circulation. Therefore hypertriglyceridemia seen with diabetes mellitus is attributed to both a reduction of lipoprotein lipase and increased production and decreased clearance of VLDL particles. Insulin deficiency increases the synthesis of cholesterol in the liver. The increased intrahepatic cholesterol concentration down-regulates the hepatocyte LDL receptor and consequently reduces the clearance of circulating LDL and HDL particles. The mechanism of hypertriglyceridemia associated with hyperadrenocorticism is probably due to stimulation of hormone-sensitive lipase with release of free fatty acids into the circulation. Similarly to diabetes mellitus, excess free fatty acids are converted into VLDL particles. In addition, glucocorticoids inhibit lipoprotein lipase activity, thereby reducing the clearance of triglyceride-rich lipoproteins.

160.3 CLINICAL FEATURES

Waxing and waning vomiting, diarrhea and/or abdominal discomfort are the most common clinical presentations associated with hypertriglyceridemia.[6] Severe hypertriglyceridemia (>1000 mg/dL) has been associated with pancreatitis, lipemia retinalis, seizures, cutaneous xanthomas, peripheral nerve paralysis, and behavioral changes. Cutaneous xanthomas, which represent lipid-laden macrophages and foam cells, are the most common manifestation of hypertriglyceridemia in the cat. Severe hypercholesterolemia has been associated arcus lipoides corneae, lipemia retinalis, and atherosclerosis.

160.4 DIAGNOSIS

Lipemic serum suggests that the animal has hypertriglyceridemia. Lactescence refers to increases of triglyceride sufficient (typically >1000 mg/dL) to cause serum or plasma samples to become milk-like in appearance and opaque. Conversely, patients with pure hypercholesterolemia do not exhibit lipemic or lactescent serum as LDL and HDL particles are too small to refract light. Blood samples to confirm hypertriglyceridemia should be obtained after a 12-to 18-hour fast. A serum sample rather than whole blood or plasma should be submitted for assessment. The sample can be refrigerated or frozen for several days without affecting the test. During assessment of the sample for hypertriglyceridemia, the laboratory should not clear the sample prior to determination of the triglyceride concentration. Clearing lipemic samples by centrifugation removes chylomicrons, which will artificially lower the triglyceride concentration.

The chylomicron test, which requires refrigeration of a sample for 12 hours, can be helpful to delineate if the lipemia is predominantly a chylomicron or VLDL defect.[6] The chylomicrons are least dense and will float to form an opaque cream layer over a clear infranatant of serum. If the hypertriglyceridemia is due to excess VLDLs, the plasma sample will remain turbid. Formation of a cream layer over a cloudy serum layer suggests both excess chylomicrons and VLDL particles.

Lipoprotein electrophoresis can be utilized to distinguish the lipoproteins and ultracentrifugation can provide a quantitative measurement of each lipoprotein class.[7] However, both of these procedures are time consuming and not routinely available. The activity of lipoprotein lipase can be assessed by the heparin release test. Serum samples for the determination of triglyceride (and if possible, lipoprotein) concentrations are obtained prior to and 15 minutes after the intravenous administration of heparin (90 IU/kg BW dog; 40 IU/kg BW cat). Heparin causes the release of lipoprotein lipase from the endothelium and stimulates the hydrolysis of triglycerides. A defect in lipoprotein lipase is suspected if there is no difference between the pre-and post-serum triglyceride concentrations.

160.5 MANAGEMENT

Prior to recommending therapy, every attempt should be taken to determine if the hyperlipidemia is primary or secondary, as lipemia secondary to an underlying disorder will typically resolve or improve with correction of the metabolic disturbance. Therefore each dog or cat requires a full history, physical examination, complete blood count, serum biochemistry panel, serum lipase, serum thyroxine concentration, and urinalysis. Additional diagnostic tests such as bile acids, abdominal ultrasound, and evaluation of the adrenocorticotropic hormone axis may be required. A recommendation to treat hyperlipidemia involves a life-long commitment by the owner and must therefore not be undertaken lightly. In general, severe hypertriglyceridemia (>500 mg/dL) mandates treatment. In this circumstance catabolic mechanisms can be assumed to be overwhelmed and the triglyceride level is sensitive to small increases from the intestine or liver. The triglyceride levels must be decreased to prevent complications including pancreatitis. In other situations, the recommendations will be influenced by additional variables, including the underlying disease process. A realistic goal of therapy is to reduce the triglyceride concentrations to less than 400 mg/dL.

Chylomicrons are produced from dietary fat, hence restriction of dietary fat is the cornerstone of therapy for hypertriglyceridemia. The dietary history should be reviewed and the diet altered to one that contains less than 20% fat on a metabolic energy basis for dogs, and less than 25% fat on a ME basis for cats (Table 160-1). Treats should be restricted to 5% of the daily caloric intake and changed to low-fat commercial varieties. Carrots or brown rice crackers are useful alternatives. In addition to providing a low-fat diet, the absolute caloric intake should be evaluated. If the pet is overweight, caloric restriction is indicated and beneficial as it decreases the

production of VLDL from excess dietary energy. The triglyceride concentration should be reevaluated after 4 weeks of feeding a low-fat diet. If the reduction in triglyceride concentration is less than ideal, the history should be reevaluated to ensure that there are no extra fat calories from treats, no access to other pet foods, and no additional family members or neighbors who are inadvertently providing the patient with fat. Unfortunately, inappropriate initial dietary selection is the most likely reason for failure to respond to nutritional therapy. A commercial diet should not be selected because the manufacturer recommends the diet for the management of hyperlipidemia. Rather, the diet should be selected because the dietary fat content is less than 20% on a metabolic energy basis. In addition, care should be given to the form of the diet as the fat content of canned and dry version of the diet may differ significantly (see Table 160-1). The medical record should also be reviewed to ensure the exclusion of underlying disorders. If commercial products are not able to control hypertriglyceridemia, then a complete and balanced ultra–low-fat (10% to 12% ME), home-prepared diet can be specifically formulated by a veterinary clinical nutritionist.

Diets rich in omega-3 fatty acids have been suggested to improve hypertriglyceridemia in humans by decreasing the production of VLDL particles. In addition, fish oils are poor substrates for triglyceride synthesizing enzymes and lead to the formation of triglyceride poor VLDL particles. Menhaden fish oil (200 mg/kg BW, dog) has been recommended for use in dogs.[6]

Treatment with drugs, all of which have toxicity, should be undertaken with particular care. In general, drugs should not be used when the serum triglyceride concentration is less than 500 mg/dL. Several classes of drugs are available for humans[8]; however, there are few reports of their use in cats and dogs. Until further studies evaluate the dose, effect, and toxicity, drug therapy is indicated only in those animals that have clinical signs associated with severe elevations in triglyceride that cannot be ameliorated by dietary therapy.

Niacin (100 mg/day, dog) reduces serum triglyceride concentrations by reduction of free fatty acid release from adipocytes and by reduction of the production of VLDL particles. Adverse effects are frequent and include vomiting, diarrhea, erythema, pruritus, and abnormalities in liver function tests. Fibric acid derivatives (clofibrate, bezafibrate, gemfibrozil, ciprofibrate, fenofibrate) lower triglyceride concentrations by stimulating lipoprotein lipase activity, in addition to reducing the free fatty acid concentration, which decreases the substrate for VLDL synthesis. In humans, the fibrates generally lower serum triglyceride concentrations by 20% to 40%. Gemfibrizol has been used in the dog (200 mg/day) and cat (10 mg/kg BW q12hr). Reported adverse effects include abdominal pain, vomiting, diarrhea, and abnormal liver function tests. The statins (lovastatin, simvastatin, pravastatin, fluvastatin, cerivastatin, atorvastatin) are HMG-CoA reductase inhibitors that primarily suppress cholesterol metabolism. As a consequence of lower intracellular cholesterol concentrations, the hepatic LDL receptor is up-regulated to increase the removal and clearance of LDL (VLDL remnant particles) from the circulation. In addition, the statins decrease hepatic production of VLDL. In humans, the statins can lower triglyceride by 10% to 15%. Adverse effects include lethargy, diarrhea, muscle pain, and hepatotoxicity.

Table • 160-1 Key Nutrients* in Diets Recommended by Selected Manufacturers for Hypertriglyceridemia

CANINE	TYPE	FAT g/1000 kcal (%ME)	PROTEIN g/1000 kcal (%ME)	ME kcal
WALTHAM Canine Veterinary Diet Low Fat	Dry	21 (18%)	66 (24%)	274/8 oz

* Information obtained from manufacturers' published information.

Unlike in humans, hypercholesterolemia rarely poses a health risk to dogs or cats. Specific therapy is only indicated if a prolonged marked increase in the serum cholesterol (>800 mg/dL) is documented because it may be associated with the development of atherosclerosis. Nutritional therapy with low fat diets is the initial treatment of choice for severe hypercholesterolemia (see Table 160-1). The addition of soluble fiber to the diet may also help to reduce cholesterol by as much as 10%. Soluble fiber interferes with the enteric reabsorption of bile acids. Consequently, the liver uses cholesterol to increase the synthesis of bile acids.

Pharmacologic agents that can be considered for the management of severe hypercholesterolemia include bile acid sequestrates, HMG-CoA reductase inhibitors, and Probucol. Bile acid sequestrates are ion exchange resins that interrupt the enterohepatic circulation of bile acids. Decreased reabsorption of bile acids stimulates the liver to synthesize bile acids and therefore uses intrahepatic cholesterol. Depletion of intrahepatic cholesterol stores stimulates the hepatic LDL receptor to increase the removal of LDL and HDL particles from the circulation. Cholestyramine (1 to 2 g PO BID) is effective at lowering cholesterol. However, its use has been associated with constipation, it interferes with the absorption of several oral medications, and it may increase hepatic VLDL synthesis with an increase triglyceride concentration. HMG-CoA reductase is the rate-limiting enzyme for cholesterol synthesis. The HMG-CoA reductase inhibitors are the most potent cholesterol lowering agents and, in humans, may reduce cholesterol concentrations by 20% to 40%. Lovastatin, 10 to 20 mg PO every 24 hours, may

be tried in dogs with persistent severe idiopathic hypercholesterolemia that does not respond to diet alone. Potential adverse effects include lethargy, diarrhea, muscle pain, and hepatotoxicity. Lovastatin should not be administered to dogs with hepatic disease. Probucol is a cholesterol-lowering agent whose mechanism of action is not completely clear. Probucol is not widely recommended for the management of hypercholesterolemia as its effect on lowering cholesterol concentration is variable and it has been associated with the development of arrhythmias.

161 CHAPTER • 161 The Principles and Implementation of Enteral Nutrition

Stanley L. Marks

The documented benefits of enteral nutritional support of hospitalized human patients and experimental animal models include maintenance of intestinal structure and function, decreased mucosal permeability to bacteria and endotoxins, and preservation of secretory immunoglobulin A concentrations in biliary tract secretions.[1,2] Despite these benefits, veterinarians may fail to respond to the nutritional needs of sick animals, perhaps because the translation of research findings into practical applications is difficult. In addition, the nutritional needs of sick animals may be neglected due to the intense focus on life-threatening medical and surgical problems. The goal of nutritional support is to provide a formula of fuels and nutrients in proportions that can be utilized by animals with maximal efficiency. Choosing the proper enteral access technique requires knowledge of the limitations and benefits of the techniques available for obtaining enteral access. The reader is encouraged to read the section on Nasoesophageal, Esophagostomy, and Gastrostomy Tube Placement Techniques for a thorough review of the techniques and complications associated with placement of these devices.

161.1 RATIONALE FOR ENTERAL NUTRITIONAL SUPPORT

Enteral feeding is indicated for animals unable to ingest adequate amounts of calories but that have sufficient gastrointestinal function to allow digestion and absorption of feeding solutions delivered into the gastrointestinal tract via an enteral feeding device. The rationale for prescribing enteral nutrition rather than parenteral nutrition (PN) is based on the superior maintenance of intestinal structure and function, safety of administration, and reduced cost of enteral alimentation. The average daily cost of TPN for maintaining the caloric requirements of a 20-kg dog at the University of California, Davis, Veterinary Medical Teaching Hospital, is approximately seven times greater (excluding catheter costs) than the cost of a commercial liquid enteral formula and a commercial canned diet. The most important stimulus for mucosal cell proliferation is the direct presence of nutrients in the intestinal lumen. Bowel rest due to starvation or administration of TPN leads to villous atrophy[3], increased intestinal permeability, and a reduction in intestinal disaccharidase activities.[4] Prolonged fasting in the stressed, critically ill animal can lead to intestinal barrier failure and increased permeability to bacteria and endotoxins.

161.2 PATIENT SELECTION FOR NUTRITIONAL SUPPORT

Efforts to assess nutritional status and attempts to decide whether nutritional support is required on the basis of a single biochemical measurement or body weight determination are simplistic and of limited value. Objective methods of assessing nutritional status such as body composition measurement (anthropometry, impedance measurements, dual energy X-ray absorptiometry) are still in their infancy in veterinary medicine, with the result that a subjective global assessment of an animals nutritional status needs to be performed. This technique is based on easily collected historical information (changes in oral intake, degree of weight loss, presence of vomiting or diarrhea) and changes found on physical examination (muscle wasting, body condition, and presence of edema or ascites).

Although body weight is routinely determined in sick animals, it is important to appreciate its limitations. The appearance of the animal cannot be equated with its state of nourishment because body weight does not differentiate between fat, lean tissue, and extracellular water. The animal's serum albumin concentration and total lymphocyte count are insensitive determinants of nutritional status because of the large number of disease processes that influence these parameters unrelated to the effects of malnutrition. Nutritional support should be

considered for animals that demonstrate recent weight loss that exceeds 10% of optimal body weight or for those whose oral intake has been or will be interrupted for more than 5 days. Animals with increased nutrient losses from chronic diarrhea or vomiting, wounds, renal disease, or burns should also be considered for nutritional support.

161.3 CALCULATION OF NUTRITIONAL REQUIREMENTS

Nutritional support provides substrates for gluconeogenesis and protein synthesis and provides the energy needed to meet the additional demands of host defense, wound repair, and cell division and growth. An estimate of an animal's nutrient requirements is needed to determine the minimum amount of food necessary to sustain critical physiologic processes (Box 161-1). The resting energy requirement (RER) is the animal's energy requirement at rest in a thermoneutral environment and in a postabsorptive state. A linear formula can be applied to determine the RER of dogs and cats weighing at least 2 kg, but no more than 15 kg. Alternatively, an allometric formula can be applied to dogs and cats of all weights.

$$\text{Linear formula: RER (kcal/day)} = (30 \times BW_{kg}) + 70$$
$$\text{Allometric formula: RER (kcal/day)} = 70\ (BW_{kg}^{0.75})$$

Accurate, direct measurements of energy expenditure in sick dogs and cats are not available. Despite the paucity of data on energy requirements of sick animals, veterinary nutritionists have recognized that the caloric requirements of critically ill animals are less than normal maintenance amounts (MER), but greater than RER. Hospitalized animals should be fed at their calculated RER initially, although their actual energy requirement is likely to change over the course of the disease process through recovery. Use of “fudge factors” extrapolated from the human literature to calculate the energy requirements of critically ill animals is discouraged, particularly in the early phase of nutritional support. Close observation of changes in body weight, physical examination findings (decreased subcutaneous fat stores, muscle wasting, and presence of edema or ascites), and ongoing losses (diarrhea, vomiting, exudative wounds) will help determine whether to increase or decrease the patients caloric intake towards the illness energy requirement (IER) or RER, respectively. The term *illness energy requirement* (IER) is used to determine caloric requirements of critically ill animals and can be determined from these formulas:

596

597

$$\text{Canine IER (kcal/day)} = 1.2 - 1.4 \times \text{RER}$$
$$\text{Feline IER (kcal/day)} = 1.1\text{–}1.2 \times \text{RER}$$

161.3.1 Box • 161-1 Enteral Feeding Worksheet for Dogs and Cats

1. Calculate resting energy requirement (RER):

   Body weight 2 to 45 kg: RER (kcal) = 30 Wt_{kg} + 70

   Body weight <2 or >45 kg: RER = 70 ($Wt_{kg}^{0.75}$)

   Body weight =___ kg

   RER =___ kcal

2. Calculate illness energy requirement (IER)*

   Illness factor = 1.2 to 1.4 for dogs

Illness factor = 1.1 to 1.2 for cats

IER = RER × illness factor

IER =___ kcal

3. Calculate amount of diet to feed:

   Daily volume to feed: IER ÷ energy density (kcal/mL)

   Daily volume =___ mL

4. Evaluate responses and modify as needed:

   Weight changes often reflect fluid dynamics in the early period after injury. Caloric requirement may need to be increased or decreased depending on animal's metabolic rate and response to nutritional support.

Modified from Marks SL: The principles and practical application of enteral nutrition, *Vet Clin North Am Small Anim Pract* 28:677, 1998.

* Animals should be fed their RER initially, and have their body weights, physical examination findings, and ongoing losses carefully evaluated before gradually increasing their caloric intake based on the IER formula.

161.4 DIET SELECTION

The type of formula to feed the patient depends on the selected route of feeding, the functional status of the gastrointestinal tract, and the animal's nutrient requirements. Other factors, such as cost, availability, and ease of use may also be important. Animals fed via nasoesophageal or jejunostomy feeding tubes are limited to receiving liquid enteral formulas that have a caloric density of approximately 1 kcal per ml. When selecting a liquid formula for feeding, veterinary professionals should pay particular attention to the amount of protein in the formula, the type of protein (intact proteins, peptides, and amino acids), and the quality of the protein. Whole egg has the highest biologic value, followed by cow milk, lactalbumin, beef, soy, and casein. Most human liquid formulas contain less than 20% protein calories, precluding their use for the long-term (longer than 2 weeks) feeding of cats. The lower-protein formulas should be supplemented with protein modules such as Promod (Ross Laboratories, Columbus, OH), Casec (Mead-Johnson, Evansville, IN) or Promagic (Animal Nutrition Laboratories, Burlington, NJ) at 15 to 30 g casein or whey powder per 8 fl oz can. Almost all human liquid enteral formulas lack taurine, an essential amino acid in cats, which necessitates its supplementation (250 mg taurine per 8 fl oz can) in this species. High-protein commercial human liquid formulations contain between 21% to 30% protein calories and include Impact (Sandoz Nutrition, Minneapolis, MN), Immun-Aid (McGaw, Inc., Irvine, CA), Alitraq (Ross Laboratories, Columbus, OH), Promote (Ross Laboratories, Columbus, OH), and Traumacal (Mead-Johnson, Evansville, IN).

Polymeric solutions contain macronutrients in the form of isolates of intact protein (casein, lactalbumin, whey, egg white), triglycerides, and carbohydrate polymers. The carbohydrates are usually glucose polymers in the form of starch and its hydrolysates and the fats are of vegetable origin. The osmolality varies between 300 and 450 mOsm/kg in solutions with a caloric density of 1 kcal/ml; however, the osmolality may reach 650 mOsm/kg in solutions with a greater caloric density. Monomeric solutions contain protein as peptides or amino acids, fat as long-chain triglycerides (LCT), or a mixture of LCT and medium-chain triglycerides (MCT), and carbohydrates as

partially hydrolyzed starch maltodextrins and glucose oligosaccharides. These solutions require less digestion and their absorption is more efficient than regular foods or polymeric solutions; however, the partially digested macronutrients contribute to the higher osmolality, which is between 400 and 700 mOsm/kg.

Commercial blenderized pet food diets are recommended for feeding via pharyngostomy, esophagostomy, or gastrostomy tubes. In select cases, the feeding of a liquid enteral formulation may be indicated (nasoesophageal or jejunostomy tube feeding). There are a number of complete and balanced veterinary enteral formulations (Table 161-1) that contain adequate amounts of protein, taurine, and micronutrients, which precludes the need for supplementation in most situations. Feeding should be delayed for 24 hours after placement of a gastrostomy tube, to allow return of gastric motility and allow formation of a fibrin seal. In contrast, feeding can be instituted immediately after esophagostomy tube placement, once the animal has fully recovered from anesthesia. Diet can be administered as bolus feedings or continuous infusion when a gastrostomy tube is used for feeding. Improved weight gain and decreased gastroesophageal reflux have been reported in human patients given continuous feedings[5], although similar studies are lacking in the veterinary literature. If continuous feeding is employed, it should be interrupted every 8 hours to determine the residual volume by application of suction to the feeding tube. If the residual volume is more than twice the volume infused in 1 hour, feeding should be discontinued for 2 hours, and the rate of infusion decreased by 25% to prevent vomiting. Treatment with metoclopramide (1 to 2 mg/kg/24 hour as a continuous infusion) may be used to enhance gastric emptying and prevent vomiting.[6]

With bolus feeding, the required daily volume of food should be divided into four to six feeds. Dogs and cats are usually fed approximately 25% of their caloric requirement on the first day of feeding, with a gradual increase of 25% of the caloric requirement per day. Most animals are able to reach their energy requirement by the fourth or fifth day of feeding. The food should be warmed to room temperature and fed slowly through the tube to prevent vomiting. Flushing of the tube with 15 to 20 mL of lukewarm water helps prevent clogging. Before each feeding, aspirate the tube with an empty syringe to check for residual food left in the stomach from the previous feeding. If more than half of the last feeding is removed from the stomach, the feeding should be skipped and residual volume rechecked at the next feeding.

597

598

Table • 161-1 Macronutrient Composition of Selected Veterinary Liquid Enteral Formulations

			NUTRIENTS (% OF TOTAL kcal)			
PRODUCT	PROTEIN TYPE	CALORIC DENSITY (kcal/ml)	PROTEIN	FAT	CARBOHYDRATE	FORMULA CHARACTERISTICS
Prescription diet Canine & Feline a/d (Hill's)	Liver Chicken Corn flour Casein	1.3	34	55	4	Isotonic, lactose free, fiber 1.3% DM, adequate taurine, fatty acid ratio (n6:n3 = 2.2:1)
Eukanuba Maximum-Calorie Canine & Feline (Iams)	Chicken Chicken by-product meal	2.1	29	66	5	Isotonic, lactose free, fiber 1.6% DM, adequate taurine, fatty acid ratio (n6:n3 = 8.3:11)
CliniCare Canine (Abbott)	80% casein 20% whey	1.0	20	55	25	Isotonic (230 mOsm/kg), lactose free, fiber free, fatty acid ratio (n6:n3 = 6.4:1)
Clinicare Feline (Abbott)	60% casein 40% whey	1.0	30	45	25	Isotonic (235 mOsm/kg), lactose free, fiber free, adequate taurine, fatty acid ratio (n6:n3 = 6.4:1)
Clinicare RF Specialized Feline (Abbott)	80% casein 20% whey	1.0	22	57	21	Isotonic (165 mOsm/kg), lactose free, fiber free, adequate taurine, fatty acid ratio (n6:n3 = 6.4:1)

Modified from Marks SL: The principles and practical application of enteral nutrition, *Vet Clin North Am Small Anim Pract* 28:677, 1998.

Jejunal feeding can be started within 6 hours of tube placement if peristalsis is present. Continuous feeding should be used with jejunostomy feeding to avoid abdominal cramping and diarrhea associated with bolus feeding via this route. Continuous infusion is recommended at an initial flow rate of 1 ml/kg/hr and increased gradually over 48 hours until the total daily volume can be given over a 12-to 18-hour period.[7]

162 CHAPTER • 162 Serology

Michael R. Lappin

***S**erology* is the study of antigen-antibody reactions in vitro. Immunoassays for use with serum, blood, or plasma can be developed to detect antigens, antibodies, or antigen-antibody complexes; some assays are only qualitative, and others are quantitative. Some assays have been adapted to detect antigen-antibody reactions in other body fluids as well. This chapter discusses the use of immunoassays in the diagnosis of infectious diseases. Commonly used terms and their definitions are listed in Table 162-1. A discussion of serologic tests used in the diagnosis of immune-mediated diseases is presented in Chapters 277 and 278.

Complement fixation, hemagglutination inhibition, serum neutralization, agglutination assays, agar gel immunodiffusion, indirect fluorescent antibody assay (IFA), enzyme-linked immunosorbent assay (ELISA), and Western blot immunoassay are commonly used methodologies. It is beyond the scope of this chapter to discuss the intricacies of each assay; the reader is directed to other chapters and publications for further information on the development, validation, and techniques for the different assays.[1–5] It is impossible to make generic statements concerning the sensitivity, specificity, predictive values, and precision of different immunoassays in general or to compare the results of one type of assay with those of another. When new immunoassays are made available, the veterinary health care worker should critically evaluate the published results of the assay prior to use.

In serologic test results, the *analytic sensitivity* defines the minimum detectable amount of the substance in question that can accurately be measured; the *analytic specificity* defines whether the substance detected cross-reacts with other substances. The *diagnostic sensitivity* is the proportion of positive test results from known infected animals; the *diagnostic specificity* is the proportion of negative test results from known uninfected animals. The *predictive value of a positive test* is the probability that a test-positive animal is diseased; the *predictive value of a negative test* is the probability that a test-negative animal is normal. The lower the prevalence of disease, the lower the predictive value of a positive test result. Disease prevalence has little effect on negative predictive values.

The following is a brief discussion of the interpretation of test results for antibody and antigen assays used with blood, serum, plasma, or other body fluids by small animal veterinary health care workers.

162.1 ANTIBODY DETECTION

Once exposed to foreign antigens, the immune system generates serum antibodies (humoral immune response). Complement fixation, hemagglutination inhibition, serum neutralization, agglutination assays, agar gel immunodiffusion, IFA, ELISA, and Western blot immunoassay are commonly used to detect serum antibodies against infectious agents. Complement fixation, hemagglutination inhibition, serum neutralization, and agglutination assays generally detect all antibody classes in a serum sample. Specific antibodies for which assays are most commonly performed include immunoglobulin M (IgM), immunoglobulin G (IgG), immunoglobulin A (IgA), and immunoglobulin E (IgE). ELISA, Western blot immunoassay, and IFA are the assay types that are usually adapted to detect specific IgM, IgG, or IgA responses. Western blot immunoassays have the potential advantage of allowing the determination of the different antigens recognized by the humoral immune responses (Figure 162-1). Comparison of IgM, IgA, and IgG antibody responses against an infectious agent can be used to attempt to prove recent or active infection. In general, immunoglobulin M (IgM) is the first antibody produced after antigenic exposure.[6] Antibody class shift to IgG occurs in days to weeks. Serum IgA responses often mirror those of IgG (Figure 162-2).

The timing of antibody testing is important. In general, serum antibody tests in puppies and kittens cannot be interpreted as specific responses until at least 8 to 12 weeks of age because of the presence of antibodies from the dam, which are passed to the puppy or kitten in colostrum. Most infectious agents can induce disease within 3 to 10 days of initial exposure; with many assays, serum IgG antibodies usually are not detected until at least 2 to 3 weeks after initial exposure. Examples include *Ehrlichia canis,*[7] feline immunodeficiency virus,[8] and *Rickettsia rickettsii*.[9] For these reasons, falsely negative serum antibody test results during acute disease are probably common in small animal practice. If specific serum antibody testing is negative initially in an animal with acute disease, repeat antibody testing should be performed in 2 to 3 weeks to assess for seroconversion. Documentation of increasing antibody titers is consistent with recent or active infection. Because of a slight potential for interassay variation, it is preferable to assess both the acute and convalescent sera in the same assay on the same day.

Many of the infectious agents encountered in small animal practice infect a large percentage of the population, resulting in serum antibody production, but they induce disease only in a small number of animals in the infected group. Notable examples include coronaviruses, *Bartonella henselae, Toxoplasma gondii,* and *Borrelia burgdorferi*.[6,8,10,11] For these examples, even though assays with good sensitivity and specificity for the detection of serum antibodies are available, the predictive value of a positive test result for the presence of disease is extremely low because antibodies are commonly detected in nondiseased animals. The diagnostic utility of some serologic tests is also limited by the presence of antibodies induced by vaccination. Examples include feline coronaviruses, some *B. burgdorferi* assays, feline herpesvirus-1 (FHV-1), feline immunodeficiency virus, parvoviruses, calicivirus, and canine distemper virus.

Positive results in serum antibody tests should always be interpreted only as evidence of present or prior infection by the agent in question. Recent or active infection is suggested by the presence of IgM, an increasing antibody titer over 2 to 3 weeks, or seroconversion (negative antibody result on the first test, positive antibody result on convalescent testing). Documentation of increasing antibody titers may suggest recent exposure to an antigen. However, the interval between the first positive result and maximal antibody titers can be very short. For example, some cats experimentally inoculated with *T. gondii* progress from the first detectable titer to the maximal titer within 1 to 2 weeks.[6]

Table • 162-1 Terms Commonly Used in Serologic Tests

TERM	DEFINITION
Affinity	The intrinsic attractiveness of one substance for another (e.g., antibody for antigen)
AGID	Agar gel immunodiffusion; an immunoassay in which the immunochemical reaction between antigen and antibody occurs in agar
Analyte	The antigen or antibody to be measured
Antibody binding site	The site of the variable region of antibodies that binds to the antigen epitope
Antigen	A substance specifically recognized by the immune system (e.g., antibody in immunoassays)
Antiglobulin	An antibody that detects another antibody
Avidity	The property of a molecular dissociation that inhibits disassociation; usually the combination of affinity and the interaction of reagents with the solid phase
Blocking	A protein or detergent used to block nonspecific reactions between reagents of an enzyme-linked immunosorbent assay (ELISA) or between reagents and the solid phase
Capture antibody	An immobilized antibody used to capture the antigen of interest from the sample
Competitive ELISA	An ELISA in which detection of the analyte is based on its ability to quantitatively inhibit the binding of a known amount of a standard analyte to a limiting amount of antibody
Conjugate	A covalent complex of two biomolecules; in ELISA, the conjugate is an antibody or antigen bound to enzyme
Direct ELISA	An ELISA in which the primary antigen-antibody interaction is measured directly because the enzyme is directly labeled to one or the other
Epitope	The portion of a biomolecule (antigen) that is specifically recognized by the antibody binding site; also called an antigenic determinant
HI	Hemagglutination inhibition
IFA	Immunofluorescent antibody assay; an immunoassay in which the primary antigen-antibody reaction is detected by a fluorescein-labeled secondary antibody
Immunoblot	An immunoassay in which the immunochemical reaction between antigen and antibody occurs on a blotting membrane
Indirect ELISA	An ELISA in which the primary antigen-antibody reaction is detected using an enzyme-labeled antiglobulin
LA	Latex agglutination
Nitrocellulose	The membrane most commonly used for immunoblot
Nonspecific binding	Binding of the conjugate in a nonimmune/nonspecific fashion, possibly resulting in a high signal and false-positive reactions
Precision	Agreement of replicate measurements within an assay or between assays; a measure of reproducibility
Reporter substance	A biomolecule that generates a signal as an indication of its presence; in ELISA, the substrate often is the reporter substance
Sandwich ELISA	A type of ELISA in which the analyte is captured by one antibody and detected by another, enzyme-linked antibody
SN	Serum neutralization
Titer	The reciprocal of the highest dilution of sample giving a predefined positive reaction in an immunoassay
Western blot (immunoassay)	A method by which molecules are electrophoretically separated on a gel, transferred to a blotting membrane, and then detected by antibodies or special stains

Detection of recent infection based on antibody testing does not always prove disease caused by the agent in question. This is especially true in affected animals with a subclinical infection. *B. burgdorferi, T. gondii,* and *B. henselae* are common examples of this. Conversely, failure to document recent or active infection based on serologic testing does not exclude a diagnosis of clinical disease. For example, many dogs with ehrlichiosis and dogs or cats with systemic fungal infections develop clinical signs of disease after serum antibody titers have reached their plateau.

Individual animals vary in the humoral responses against specific antigens. Some animals are high responders and produce large concentrations of specific antibody, whereas others do not. Thus the magnitude of an antibody titer does not definitely document that an antigenic exposure was recent, active, or associated with clinical disease. This is particularly true for the IgG class of antibody and for agents resulting in persistent infections. For example, many healthy cats experimentally inoculated with *T. gondii* have had IgG antibody titers greater than 1:10,000 even 6 years after the last inoculation.[6] Because no antibody test by itself can prove the presence of disease, clinical diagnosis of an infectious disease usually includes the following factors:

- Clinical signs referable to the agent
- Serologic evidence of exposure to the agent
- Exclusion of other causes of the clinical syndrome
- Demonstration of the agent or of response to treatment

Figure 162-1 Example of a Western blot immunoassay. The bands that have developed in the suspect serum lanes are consistent with an antigen-antibody reaction. Comparison to the molecular mass standards allows determination of the approximate size of the antigen inducing the immune response.

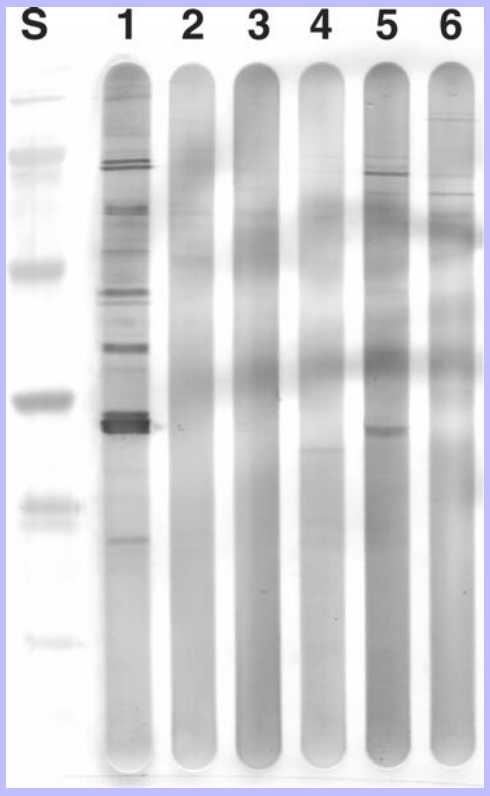

Figure 162-2 Graphic representation of IgM, IgG, and IgA immune responses characteristic for cats after antigenic exposure in week 0.

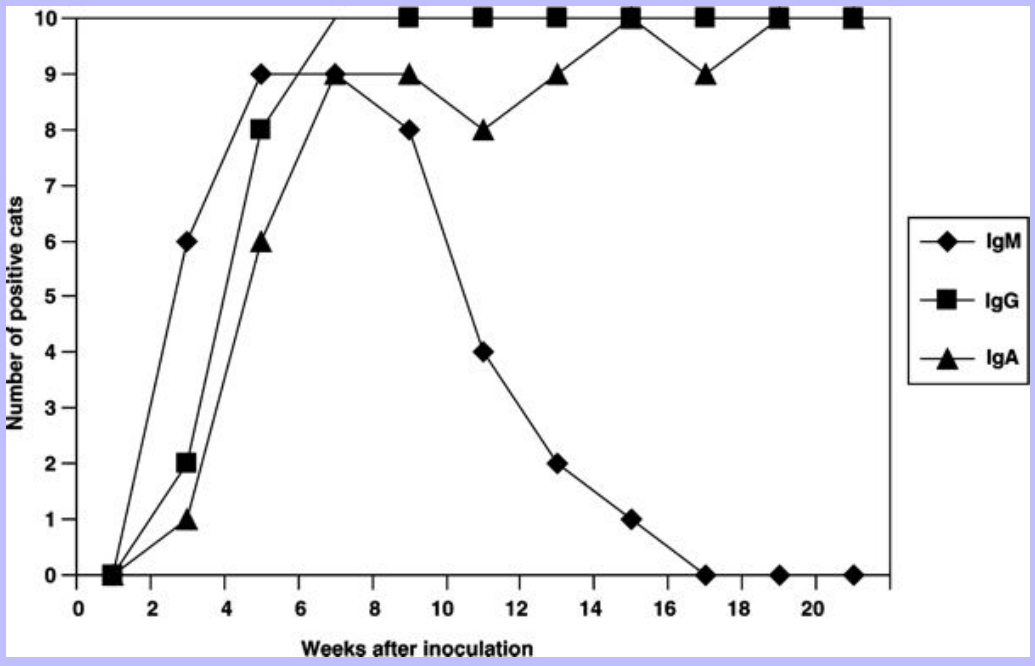

601

603

162.2 ANTIGEN DETECTION

Immunoassays can be used to measure any substance against which an antibody can be generated. Examples include antigens of infectious agents, cell-associated antigens (including tumors), receptors, hormones, and drugs. Positive results in immunoassays that detect the presence of antigens of an infectious disease agent document that the animal is currently infected. The presence of antibodies denotes current or previous infection.

Immunoassays are commercially available for the detection of *Dirofilaria immitis,*[12] feline leukemia virus (FeLV),[13] and *Cryptococcus neoformans*[14] antigens in serum, plasma, or blood. The performance of specific assays may vary with the different fluids; in general, serum gives the most consistent results. For the most part, the sensitivities and specificities of the infectious disease antigen assays are good. *D. immitis* antigen test results can be negative in some animals with low worm burdens or single sex infections; this is particularly true for cats.[12] Feline leukemia virus antigen test results can be negative in cats with localized or sequestered infection (latent). Serum-or plasma-based feline leukemia virus antigen tests can also yield transiently positive results in cats that are limiting infection; the results for healthy, ELISA-positive cats should always be confirmed by repeat ELISA testing or by IFA testing.[14] Because clinically normal animals can be antigen positive by ELISA, the positive predictive value for disease is not 100%, particularly if the prevalence of disease is low. Positive feline leukemia antigen test results also do not prove immunodeficiency. In dogs and cats with localized cryptococcosis, serum antigen test results can be negative.

162.2.1 Body Fluids

Some infectious agents induce disease of the eyes and central nervous system (CNS). Documentation of agent-specific antibodies in aqueous humor, vitreous humor, or cerebrospinal fluid (CSF) can be used to prove the involvement of these tissues. Quantification of ocular and CSF antibodies is difficult to interpret if serum antibodies and inflammatory disease are present, because serum antibodies leak into ocular fluids and CSF in the presence of inflammation. Detection of local production of antibodies in the eye or CNS has been used to aid the diagnosis of canine distemper virus infection (see Chapter 169) and feline toxoplasmosis (see Chapter 169). The following ratio is a method of proving local antibody production by the eye or CNS:

$$\frac{\text{Aqueous humor or CSF specific antibody}}{\text{Serum specific antibody}} \times \frac{\text{Serum total antibody}}{\text{Aqueous humor or CSF total antibody}}$$

A ratio greater than 1 suggests that the antibody in the aqueous humor or CSF was produced locally. This formula has been used extensively in the evaluation of cats with uveitis. Approximately 60% of cats with uveitis in the United States have *T. gondii*–specific IgM, IgA, or IgG values greater than 1.[6,15] This technique also was used to help prove that FHV-1[16] and *B. henselae*[17] are causes of uveitis in cats.

Feline leukemia virus antigen can be detected in saliva, tears, and cells from the bone marrow or direct blood smear.[13] The sensitivity and specificity of FeLV tests using tears and saliva are less than for those using serum. Detection of FeLV antigen in cells by fluorescent antibody testing generally denotes persistent infection. *T. gondii* antigens have been detected in aqueous humor and CSF, but their presence does not correlate with the presence of disease.[6] The *C. neoformans* latex agglutination procedure for detection of antigen can also be performed on aqueous humor, vitreous humor, and cerebrospinal fluid.

Immunoassays are available for the detection of parvovirus, *Cryptosporidium parvum,* and *Giardia spp*. in feces. The commercially available parvovirus assay was titrated for use with canine feces and canine parvovirus, but generally it can detect panleukopenia antigen in the feces of infected cats as well. Sensitivity appears to be good with parvovirus fecal antigen tests, but positive test results are not specific for natural exposure because modified live parvovirus vaccines are shed into feces, giving transiently positive results (see Chapter 169). The currently available assays for the detection of *C. parvum* and *Giardia spp*. in feces were titrated for human isolates and feces. Minimal sensitivity and specificity results are available for these assays when they are used with feces from small animals (see Chapter 168). If these assays are used, the results should be interpreted with results from fecal examination techniques for oocysts *(Cryptosporidium)* or cysts *(Giardia)*.

163 CHAPTER • 163 Canine Vaccination

Richard B. Ford

The recent publication of the *2003 Canine Vaccine Guidelines and Recommendations*[1] is the first such effort intended to provide a unified consensus reference on canine vaccination for the veterinary profession.

As published, the *Guidelines* address 15 types of canine vaccine licensed for use in the United States and provide critical information pertinent to the development and implementation of vaccination protocols for dogs. The *Guidelines* are *not* intended to represent vaccination *standards* for dogs nor do they define a uniform vaccination protocol for use in clinical practice. As new information is gained and as new vaccines are licensed for use in dogs, these *Guidelines* will be updated.

The context of the *2005 Canine Vaccine Guidelines* centers on vaccine selection and frequency of use. Additional supportive information includes an overview of immunology as it pertains to vaccination, the role of serologic testing in determination of the need to administer booster vaccines to individual patients, vaccine adverse events, and pertinent legal and liability issues related to administering vaccines. The Canine Vaccine Guidelines outlined by the Task Force are summarized in Table 163-1. The reader is encouraged to consult the full text of the Guidelines for further information on individual vaccine types and supporting literature.[2]

163.1 VACCINE SELECTION

Vaccination guidelines published for cats as well as dogs have endorsed terms (*core* and *noncore*) that categorize vaccine types (not individual products) using criteria such as health risk associated with infection, disease incidence and severity, and vaccine efficacy. *Core* vaccines are generally defined as those vaccines that should be administered to *every* dog (and every cat) that is 6 months of age or younger or is not known to have received prior vaccination. These vaccines are deemed particularly important because the infections they prevent are associated with significant morbidity and mortality, are widely distributed, or are zoonotic. The Canine Vaccine Task Force has designated vaccines against canine distemper, canine parvovirus, canine adenovirus-2, and rabies virus as *core*.

Vaccines defined as *noncore* (or “optional”) are those that should be administered only after consideration of the risk an individual dog has for exposure to a defined infectious agent. Factors such as geographic distribution of the disease (e.g., Lyme borreliosis), age of the patient (puppy versus adult), and lifestyle (strict indoor versus free-roaming) are considered in the decision to administer, or not administer, noncore vaccines. Vaccines placed in this category are recommended when it is the objective to protect individual dogs against less common, or less severe, infections that are either self-limiting or amenable to treatment. The Canine Vaccine Task Force has designated vaccines against measles (distemper-measles), canine parainfluenza, *Leptospirosis* spp., *Bordetella bronchiseptica*, and *Borrelia burgdorferi* as *noncore*.

Additionally, the Task Force has designated vaccines against *Giardia* spp., canine coronavirus, and canine adenovirus-1 (canine hepatitis) as “not generally recommended.” The basis for such designation is based on information discussed in detail within the context of the *Guidelines*. Reasons for placing a particular vaccine in this category have been based on one or more of the following: the disease a vaccine is intended to prevent is either of little or no clinical significance (e.g., coronavirus), the vaccine is known to be associated with potentially serious adverse events (e.g., adenovirus-1), or the vaccine does not prevent infection (e.g., *Giardia* spp.).

The Canine Vaccine Task Force acknowledges the fact that all veterinarians may not agree with which vaccines belong in which category. For that reason, the *Canine Guidelines* have been written to support individual clinicians and practices in designation of which vaccines should be given to all dogs presented to the practice and which vaccines are administered only on the basis of a defined health risk assessment. Veterinarians are therefore encouraged to designate, for the individual practice, which vaccines should be *core* and which *noncore*. The decision to administer, or *not* to administer, a vaccine categorized as *noncore* rests with the individual clinician after interviewing the pet owner and assessing reasonable risk for exposure. For example, the Canine Vaccine Task Force designated canine adenovirus-2 vaccine as *core* and the canine parainfluenza vaccine as *noncore*. However, the majority of parainfluenza vaccine products on the market today are combined with canine adenovirus-2. It is therefore quite reasonable for an individual practice to designate *both* canine adenovirus-2 and parainfluenza vaccines as *core* when developing a vaccine protocol.

163.2 FREQUENCY OF VACCINE USE

Among the most significant recommendations made by the Canine Vaccine Task Force is that, despite traditional recommendations, certain vaccines, when administered to adult dogs as a booster vaccination, may be administered at intervals of 3 years without degradation of protection or increased risk if exposed to the virulent agent. In fact, limited studies involving most core vaccines support a minimum duration of immunity (DOI) of 5 to 7 years. Recommendations pertaining to *initial* vaccination intervals for puppies and adult dogs (not previously vaccinated) remain unchanged.

Current information on DOI, as presented in the full text of the *Guidelines,* supports the recommendation for 3-year booster vaccination intervals for the following vaccines: canine distemper (modified-live and recombinant), parvovirus (modified-live), canine adenovirus-2 (modified-live), and parainfluenza virus.

Obviously the actual DOI for any vaccine is influenced by such factors as the vaccine manufacturing process, route of administration, concentration of antigen in the product, product handing, health status of the patient at time of vaccination, and genetic variances in an individual animal's ability to response to a vaccine.

Table • 163-1 Canine Vaccine Recommendations—2005

VACCINE	PRIMARY VACCINATION (PUPPY) ≤16 WEEKS	PRIMARY VACCINATION (ADULT) >16 WEEKS	REVACCINATION (BOOSTER) RECOMMENDATIONS	COMMENTS
Canine Distemper Virus (MLV)	Administer one dose at 6–8 weeks, then 9–11 weeks, then 12–14 weeks of age	1 dose is protective	First booster is administered 1 year following the last dose of the initial (puppy) series. **Additional boosters are administered every 3 years thereafter.**	***Highly Recommended:***Despite manufacturer's annual booster recommendations, studies have shown that adult dogs challenged 7 years (Rockborn Strain) and 5 years (Onderstepoort Strain) following MLV vaccination were protected. A booster vaccination interval of every 3 years among adult dogs in protective.
CORE				
rCanine Distemper Virus (**r**CDV) (recombinant vaccine)	Administer one dose at 6–8 weeks, then 9–11 weeks, then 12–14 weeks of age	2 doses, 2–4 weeks apart	Booster annually-or- **Booster may be administered (see comments section) every 3 years.**	***Recommended:***May be used interchangeably or as an alternative to the MLV-CDV vaccine. Does not provide “sterile” immunity and may take longer to protect immunologically naïve dogs. Minimum demonstrated. Duration of Immunity (DOI) for **r**CDV is >2 years. Does not routinely provide sterile immunity and may take longer to protect immunologically naïve dogs. The vaccine is not recommended where the threat of exposure to CDV may be significant (e.g., shelters; pet stores). NOTE: A vaccination program that includes MLV-CDV vaccine for the initial vaccination followed by booster vaccination with **r**CDV would provide excellent protection; revaccination with **r**CDV every 3 years would then be reasonable.
CORE VACCINE (alternative to MLV CDV)				

Distemper-Measles Virus (MLV) **Administer by the INTRA-MUSCULAR route only**	One dose between 4 and 12 weeks of age⋯ **only**. (Follow with one dose of MLV-CDV-or- 2 doses of **r**CDV vaccine after 12 weeks of age)	Not recommended for use in dogs over 12 weeks of age	Booster vaccination is **NOT** recommended.	**Optional.** ***Not Recommended for Routine Use.*** Intended to provide *temporary* protection in young dogs only. Indicated for use in households/kennels where distemper is a recognized problem. **Do not administer to female dogs over 12 weeks of age.** **Not recommended for use in ANY dog over 12 weeks of age.** NOTE: If used in adults, the vaccine may result in maternal measles virus antibody that would be passed to offspring. This maternal antibody would interfere with subsequent vaccination against distemper. This vaccine will not immunize dogs if given by the subcutaneous route.
NONCORE				
Canine Parvovirus (MLV)	Administer one dose at 6–8 weeks, then 9–11 weeks, then 12–14 weeks of age	1 dose (however, recommend-ing 2 doses, 3–4 weeks apart is acceptable)	First booster is administered 1 year following the last dose of the initial (puppy) series. **Additional boosters are administered every 3 years thereafter.**	***Highly Recommended:*** Although annual boosters are recommended by vaccine manufacturers, studies have shown protection against challenge up to 7 years post-vaccination with MLV vaccine.
CORE				

Canine Parvovirus (killed)	Administer one dose at 2, 3 and 4 months of age	2 doses, 3–4 weeks apart	Annual NOTE: Studies are not currently available demonstrating an extended DOI for killed CPV products. NOTE: Puppies completing the initial series with an MLV CPV vaccine and revaccinated 1 year later with an MLV CPV vaccine could be vaccinated every 3 year thereafter with the KILLED virus vaccine.	***Recommended:***A suitable to the MLV alternative canine parvovirus vaccine in a LOW-risk environment, ALTHOUGH most practices routinely use the MLV vaccine. NOTE: Killed parvovirus products are susceptible to maternal antibody interference in puppies as old as 16 to 18 weeks of age. NOTE: Studies have shown protection against challenge 16 months post-vaccination in dogs only vaccinated with killed vaccine.
NON-COREan alternative to the MLV vaccine				
Canine Adenovirus-1 (CAV-1) (MLV and killed)	Administer one dose at 6–8 weeks, then 9–11 weeks, then 12–14 weeks of age	2 doses, 2–4 weeks apart (Killed vaccine) 1 dose (MLV vaccine)	Annual (manufacturer recommendation)	***Not Recommended.***Infectious Canine Hepatitis is uncommon in the U.S. Considering the low (to absent) prevalence, the risk of “hepatitis Blue-Eye” reactions, and the fact that CAV-2 will cross-protect against CAV-1, use of vaccines containing CAV-1 are notrecommended.
NOT RECOM-MENDED				***Caution:*** **At least 9 OTC vaccines Caution: At least 9 OTC vaccines (available to pet owners without a prescription) are currently on the market. Three of those vaccines contain a combination of BOTH CAV-1 and CAV-2!**

Canine Adenovirus-2 (CAV-2) (MLV-parenteral or topical) (Killed)	Administer one dose at 6–8 weeks, then 9–11 weeks, then 12–14 weeks of age	2 doses, 2–4 weeks apart (Killed vaccine) 1 dose (MLV vaccine)	First booster is administered 1 year following the last dose of the initial (puppy) series. **Additional boosters are administered every 3 years thereafter.**	***Highly Recommended.*** Demonstrated cross protection against canine hepatitis (CAV-1) and CAV-2, one of the agents known to be associated with infectious tracheobronchitis (ITB). Usually combined with CDV and CAV vaccine. *Currently this product is not available as a monovalent vaccine.* Adult dogs challenged 7 years following CAV-2 MLV vaccination were found to be protected against the more virulent CAV-1.
CORE				
Parainfluenza Virus (CpiV) (MLV-parenteral or topical)	Administer one dose at 6–8 weeks, then 9–11 weeks, then 12–14 weeks of age	1 dose is adequate (However, recommend-ing 2 doses, 3–4 weeks apart is acceptable.)	*Parenteral:* First booster is administered 1 year following the last dose of the initial (puppy) series. **Additional boosters are administered every 3 years thereafter.** *Intranasal:* Available only in combination with those *Bordetella bronchiseptica* indicated for intranasal administration. **Unpublished data suggests the DOI may persist beyond 1 year.**	***Recommended.***Usually combined with CDV and CAV vaccine. Currently this product is not available as a monovalent vaccine. Parenterally administered vaccine is less effective than topically (intranasal) administered vaccine. DOI by challenge has been shown to be at least 1 year (unpublished) for topical vaccine. Parenteral CPiV vaccine is available in combination with CDV, CPV, and CAV-2 vaccines. Intranasal CPiV vaccine is available In combination with *B. bronchiseptica* and CAV-2 vaccines.
NONCORE				

Bordetella bronchiseptica (killed bacterin)-Parenteral	Administer one dose at 6–8 weeks, then 10–12 weeks of age	2 doses, 2–4 weeks apart	Annual	***Optional.***Recent studies suggest the parenteral *B. bronchiseptica* vaccine may be more efficacious than the topical vaccine when administering boosters to adult dogs. The DOI is believed to be less than 1 year. There is no clear advantage in administration of the parenteral and the topical *B. bronchiseptica* simultaneously.
NONCORE *Bordetella dogs bronchiseptica* (live avirulent bacterin) + Parainfluenza Virus (MLV) **TOPICAL (intranasal) USE ONLY**	Administer a single dose as early as a 3 WEEKS OF AGE. (See product literature for age recommendations.) If topical vaccine is administered prior to 5–6 weeks of age, it should be administered again after 6 weeks of age and at least 2 weeks following the last dose.	Not stipulated, although a single dose is recommended.	Annual ⋯ if notvaccinated within the last 6 months, a booster is recommended 1 wk prior to known exposure (e.g., boarding, showing)	***Optional-Recommended***for housed in kennels, shelters, pounds; prior to boarding in kennels. Transient (3–10 days) coughing, sneezing, or nasal discharge occurs in a small percentage of vaccinates. Antimicrobial therapy may be indicated (Rx Doxycycline, 5–7 days) to manage post-vaccination upper respiratory signs (persistent cough and nasal discharge). DOI is believed to be approx. 10 months for *B.bronchiseptica*. NOTE: Topically administered vaccines for canine infectious tracheobronchitis may provide a superior local immune response compared to parenterally administered vaccines.
NONCORE *Bordetella bronchiseptica* (live avirulent bacterin) + Parainfluenza Virus (MLV) + Canine Adenovirus-2 (MLV) **TOPICAL (intranasal) USE ONLY OPTIONAL**	Administer a single dose at ≥8 weeks of age. Some manufacturers may recommend administration as early as 3 to 4 weeks of age. This is recommended only when extremely high risk of exposure is likely.	A single dose is recommended.	Annual ⋯ if notvaccinated within the last 6 months, a booster is recommended 1 wk prior to known exposure (e.g., boarding, showing)	***Recommended***for dogs considered to be at risk of exposure to any of the pathogens listed. NOTE: Topically administered vaccines for canine infectious tracheobronchitis may provide a superior local immune response compared to parenterally administered vaccines. DOI as noted above for individual vaccines.

Borrelia burgdorferi; **r**Lyme borreliosis (recombinant) Outer Surface Protein A (OspA) **NONCORE**	Initial dose may be given at 9 weeks of age and a required second dose 2–4 weeks later. Optimal age for the initial dose is ≥3 months with a second dose 2–4 weeks later.	2 doses, 2–4 weeks apart	Annual (The Task Force has recommended that, depending on geographic location, the vaccine be administered prior to the start of the tick season.)	***Optimal. NOTE:*** Lyme disease has limited regional prevalence; therefore recommendation for use is limited to dogs known to have a high risk of exposure. The minimum DOI for the recombinant vaccine is 1 year based on challenge.
Borrelia burgdorferi; Lyme borreliosis (killed whole bacterin) **NONCORE**	Initial dose may be given at 9 weeks of age and a required second dose 2–4 weeks later. Optimal age for the initial dose is ≥3 months with a second dose 2–4 weeks later.	2 doses, 2–4 weeks apart	Annual (The Task Force has recommended that, depending on geographic location, the vaccine be administered prior to the start of the tick season.)	***Optional.*** Lyme disease has limited regional prevalence. Recommendation for use is limited to dogs with a known high risk of exposure, preferably dogs living in the Northeastern U.S. and the upper Midwest (Wisconsin, Michigan) or perhaps those traveling to endemic areas when the risk of tick exposure is considered to be high. Minimum DOI based on challenge studies is 1 year.

	Canine coronavirus (killed and MLV)	Administer one dose every 2–4 weeks of age until 12 weeks of age (MLV and killed). The *killed* vaccine may be administered as early as 6 weeks of age followed by an additional dose every 2–3 weeks with the final dose at 12 weeks of age.	1 dose (if using MLV) 2 doses, 2–3 wks apart (if using killed) (The Task Force does not recommend the use of CCV vaccine in adult dogs since neither need nor benefit has been demonstrated in challenge studies.)	Annual (manufacturer recommendation) Neither product is recommended until clinical benefit demonstrated over combined vaccines (e.g., CPV and CDV only) that do not contain CCV antigen.	Prevalence of clinical cases of confirmed canine coronavirus infection does not justify routine inoculation of all dogs. Clinical infections are most likely to occur in puppies less than 6 weeks of age. Clinical signs are mild or not apparent and typically resolve spontaneously. It is recommended that animal shelters NOT utilize CCV vaccine in routine vaccination programs due to additional costs incurred by doing so and the lack of defined benefit. Experience has shown no additional increase in infectious enteritis among adults or puppies subsequent to discontinuing CCV vaccine. The DOI for CCV vaccine can not be determined since control dogs that are challenged do not become ill. Neither the MLV CCV vaccine nor the killed CCV vaccine has been shown to significantly reduce disease caused by a CCV + CPV challenge.
	NOT GENERALLY RECOMMENDED				

	Leptospira interrogans (L. canicola combined with *L. icterohaem-orrhagiae)* (killed bacterin) (Also available with serovars *grippotyphosa and pomona*)	Administer 1 dose at 12 weeks and a second at 16 weeks of age. NOTE: For optimal response, do not administer to dogs less than 12 weeks of age.	2 doses, 2–4 weeks apart	Annual Some authors recommend a booster every 6 months in dogs known to be at *significant* risk of exposure, i.e., documentation of infections in the practice population or area. Arbitrary administration of leptospirosis vaccines every 6 months is NOT recommended.	***Optional.***NOTE: Disease prevalence is likely to vary for each serovar. Vaccine recommendations are therefore difficult to make due the lack of information on prevalence of specific serovar infections among dogs living in various geographic regions of the U.S. Anecdotal reports from veterinarians and breeders suggest that the incidence of post-vaccination reactions (acute anaphylaxis) in puppies (less than 12 weeks of age) and small breed dogs is high. Reactions are most severe in young (<9 weeks of age) puppies. Routine use of the vaccine should be delayed until dogs are ≥12 weeks of age. Minimum DOI based on challenge studies has been shown to be approximately 12 months for serovars *L. canicolaand L. icterohaemorrhagiae*. Efficacy, however, is <75%. (Data is not available on theDOI for *L. grippotyphosa and L.pomona*)
NONCORE					

Giardia lamblia (killed)	An initial dose may be given at 8 weeks of age; a second dose should be given 2–3 weeks later.	2 doses, 2–4 weeks apart	Annual (manufacturer's recommendation) The Task Force recommends that boosters are NOT necessary in dogs ≥1 year of age.	***Not Recommended***. The vaccine may prevent oocyst shedding but does not prevent infection. Infection in puppies (and kittens) is often subclinical. Although giardiasis is the most common intestinal parasite among people in the U.S. the source of human infection is contaminated water. Infections in dogs and cats are not considered to be zoonotic. The vaccine does NOT prevent infection, therefore a minimum DOI based on challenge is not reported.
NOT GENERALLY RECOM-MENDED				
Rabies **1-year** (killed) ROUTE OF ADMINISTRA-TION MAY NOTBE OPTIONAL–see product literature for details.	Administer 1 dose as early as 3 months of age.	Administer a single dose.	Annual. State, provincial, and/or local laws apply. The **1-year** rabies vaccine may be used as a booster vaccine when dogs are required, in accordance with local statutes, to be vaccinated annually against rabies.	***Required.*** MLV vaccines are no longer available for administration in the U.S. State and local statutes govern the frequency of administration for products labeled as "1-Year Rabies." NOTE: The Rabies (1-year) vaccine is generally administered as the initial dose followed, 1 year later, by administration of the Rabies (3-year) Vaccine. State and local statutes may dictate otherwise.
CORE				

Rabies **3-year** (killed) ROUTE OF ADMINISTRA-TION MAY NOTBE OPTIONAL—see product literature for details.	Administer 1 dose as early as 3 months of age. NOTE: The 3-year rabies vaccine may be used as an alternative to the 1-year rabies vaccine for initial and subsequent doses. Local statutes apply.	Administer a single dose. NOTE: The 3-year rabies vaccine may be used as an alternative to the 1-year rabies vaccine for initial and subsequent doses. Local statutes apply.	The **second** rabies vaccination is recommended 1-year following administration of the initial dose regardless of the animal's age at the time the first dose is administered. Depending on local statutes, booster vaccines should be administered annually or every 3 years thereafter.	**Required.** State and local statutes govern the frequency of administration for products labeled as Rabies (3-year) ⋯ these statutes vary throughout the U.S. and Canada. NOTE: The Rabies (1-year) vaccine is generally administered as the initial dose followed, 1 year later, by administration of the Rabies (3-year) Vaccine. State and local statutes may dictate otherwise. The Task Force recommends that every effort should be made to change laws that require vaccination with the 3-year rabies vaccine at any interval less than 3 years. Doing so does not increase efficacy and may actually be associated with adverse events.
CORE				
NOTE: Letter designation "**r**" preceding the name of the antigen indicates a recombinant vaccine. *NOTE: Route of administration is SQ or IM unless otherwise noted by the manufacturer.*				

605

611

163.3 CONCLUSION

In the absence of specific and reliable tests for immunity to infectious disease, each veterinarian must accept the responsibility of developing a rational vaccination protocol that, based on health risk profiling and vaccine(s) available, will best protect the individual patient at the most appropriate stages of life. The *Canine Vaccine Guidelines* have been specifically written to support safe, effective, and rational vaccination decisions.

164 CHAPTER • 164 Feline Vaccinations

James R. Richards

The overall objectives of feline vaccination are to vaccinate the largest possible number of cats in the population at risk, vaccinate each cat no more frequently than necessary, and vaccinate only against infectious agents to which the cat has a realistic risk of exposure and subsequent development of disease. Kittens less than 4 months of age are usually more susceptible to infection and disease than are adult cats, and they are the principle targets for vaccination.[1]

164.1 VACCINATION EFFICACY

The success of vaccination against an infectious agent rests upon the ability of the immune system to protect against the disease in question.[2] Vaccines against agents that do not establish persistent infections (e.g., feline panleukopenia virus) are the most successful. Vaccines against agents characterized by persistent infections (e.g., feline herpesvirus [FHV], feline calicivirus), that evade host defense mechanisms (e.g., feline leukemia virus [FeLV], feline immunodeficiency virus [FIV]), that mutate as they replicate within the host (e.g., FIV, feline calicivirus, feline coronavirus), or that use normal host defenses to cause disease (e.g., feline coronavirus) are generally less successful.

Vaccines do not induce the same degree of protection in all animals, nor do most vaccines induce complete protection from either infection or disease. Factors that negatively affect an animal's ability to respond to vaccination include maternal antibody interference, congenital or acquired immunodeficiencies, concurrent disease, inadequate sanitation, immunosuppressive medication, and stress due to overcrowding.[3] An optimal response to vaccination cannot be obtained until the influence of these factors is reduced.

Table • 164-1 Guidelines for Administration of Feline Vaccines

ANTIGEN	VACCINE TYPES[a]	PRIMARY VACCINATION		BOOSTER VACCINATION	COMMENTS
		Cats <12 Weeks Old	Cats ≥12 Weeks Old		
Feline parvovirus[b]	MLV vaccine for parenteral administration MLV vaccine for topical administration Adjuvanted inactivated-virus vaccine for parenteral administration	If ≥6 weeks old, clinician should vaccinate at initial visit and every 3 to 4 weeks until ≥12 weeks old[c]	2 doses, 3 to 4 weeks apart	1 year after primary vaccination, then no more frequently than every 3 years	*Highly recommended for all cats;* in most cats, protection derived after administration of booster vaccination 1 year after primary vaccination is sustained for at least 3 years and probably 5 to 6 years or more; MLV vaccines should *not* be administered to pregnant queens or kittens <4 weeks old
Feline herpesvirus-1 (FHV-1) and feline calicivirus	Combined MLV vaccine for parenteral administration Combined adjuvanted inactivated-virus vaccine for parenteral administration	If ≥6 weeks old, clinician should vaccinate at initial visit and every 3 to 4 weeks until ≥12 weeks old[c]	2 doses, 3 to 4 weeks apart	1 year after primary vaccination, then every 3 years	*Highly recommended for all cats;* MLV vaccine should *not* be administered to pregnant queens
FHV-1 and feline calicivirus	Combined MLV vaccine for topical administration	If ≥6 weeks old, clinician should vaccinate at initial visit and every 3 to 4 weeks until ≥12 weeks old[d]	1 dose	1 year after primary vaccination, then every 3 years	*Highly recommended for all cats;* may be used as an alternative to the parenteral product; may be preferable to parenterally administered vaccines in cats reared in or entering environments in which viral upper respiratory tract disease is endemic (e.g., some catteries, boarding facilities, shelters); MLV vaccine should *not* be administered to pregnant queens

Rabies	Adjuvanted inactivated-virus vaccine for parenteral administration every year[e f]	Not eligible for vaccination	1 dose	1 year after primary vaccination, then every year[e]	*Highly recommended for all cats*; rabies vaccination of cats is required by law in some regions of the country, and veterinarians should comply with state and local statutes regarding type of vaccine to be used and vaccination interval
Rabies	Adjuvanted inactivated virus vaccine for parenteral administration every 3 years[e]	Not eligible for vaccination	1 dose	1 year after primary vaccination, then every 3 years[e]	*Highly recommended for all cats*; rabies vaccination of cats is required by law in some regions of the country, and veterinarians should comply with state and local statutes regarding type of vaccine to be used and vaccination interval
Rabies	Canarypox virus–vectored recombinant vaccine for parenteral administration	1 dose to cats as young as 8 weeks old	1 dose	1 year after primary vaccination, then every year	The *recombinant* rabies virus vaccine can be used as an alternative to other products approved for annual use; this product does not contain an adjuvant, and postvaccination inflammation at the vaccine site appears minimal; however, whether use of this product will be associated with a decreased likelihood of vaccine-associated sarcoma formation is not presently known
Feline leukemia virus (FeLV)	Adjuvanted and nonadjuvanted inactivated-virus vaccines for parenteral administration	2 doses, 3 to 4 weeks apart to cats as young as 8 weeks old[f]	2 doses, 3 to 4 weeks apartf	Annually	Recommended for cats that are notrestricted to a closed, indoor, FeLV-negative environment; most important for cats <16 weeks old;[d] not recommended for cats ≥16 weeks old with minimal to no risk of exposure to FeLV-infected cats

Chlamy-dophila felis	MLV vaccine for parenteral administration Adjuvanted inactivated vaccine for parenteral administration	2 doses, 3 to 4 weeks apart to cats as young as 9 weeks old	2 doses, 3 to 4 weeks apart	Annually	Not recommended for routine use; can be considered for use in cats in multiple-cat environments where *C. sittaci* infections associated with clinical disease have been documented
Feline infectious peritonitis (FIP) virus	MLV vaccine for topical administration	Not approved for cats <16 weeks old	2 doses, 3 to 4 weeks apart to cats ≥16 weeks old	Annually	Not recommended; at this time, insufficient evidence exists to support the conclusion that the vaccine induces clinically relevant protection
Microsporum canis	Adjuvanted inactivated vaccine for parenteral administration	Not approved for cats <16 weeks old	First dose administered SC to cats ≥16 weeks old; second dose administered SC 12 to 16 days after the first dose; third dose administered SC 26 to 30 days after the second dose	Not stipulated	Not recommended for routine use; vaccination may be considered as one component of a comprehensive control program in multiple-cat environments in which *M. canis* infection is endemic or as adjunctive treatment to hasten resolution of clinical signs in individual cats
Bordetella bronchi-septica	MLV vaccine for topical administration	1 dose (0.2 mL) intranasally to cats ≥4 weeks old	1 dose (0.2 mL) intranasally	Not stipulated	Not recommended for routine use; vaccination may be considered for cats entering or residing in multiple-cat environments where *B. bronchiseptica* infections associated with clinical disease have been documented[g]
Giardia lamblia	Adjuvanted inactivated vaccine for parenteral administration	2 doses, 3 to 4 weeks apart to cats as young as 8 weeks old	2 doses, 3 to 4 weeks apart	Annually	Not recommended for routine use; vaccination may be considered as one component of a comprehensive control program in multiple-cat environments in which *G. lamblia* infections associated with clinical disease have been documented
Feline immuno-deficiency virus (FIV)	Adjuvanted inactivated whole virus vaccine for parenteral administration[h]	3 doses, 2 to 3 weeks apart to cats as young as 8 weeks old	3 doses, 2 to 3 weeks apart	Annually	Not recommended for routine use; vaccination may be considered for cats not restricted to a closed, FIV-negative environment.[i]

MLV, Modified-live virus; *SC,* subcutaneously.

Adapted from the American Association of Feline Practitioners and Academy of Feline Medicine Advisory Panel on Feline Vaccines. Used by permission.

a. Parenteral vaccines containing antigens limited to feline panleukopenia virus, FHV, and feline calicivirus (with or without *Chlamydophila felis*) should be administered as distally as possible on the lateral right forelimb. Monovalent parenteral FIV vaccines should be administered as distally as possible over the left forelimb. Vaccines containing rabies virus antigen (plus any other antigen) should be administered as distally as possible on the lateral right hindlimb. Vaccines containing FeLV antigen (plus any other antigen except rabies virus) should be administered as distally as possible on the lateral left hindlimb.

b. Cause of feline panleukopenia.

c. For kittens that are orphaned or at high risk of exposure, vaccination when as young as 4 weeks old may be indicated.

d. For kittens that are orphaned or at high risk of exposure, vaccination when as young as 2 weeks old may be indicated.

e. A specific route of administration may be required; see product information for details. Most often, the product approved for use annually is given for initial vaccination, followed 1 year later and every 3 years after that by administration of the product approved for use every 3 years; however, vaccination interval must comply with local and state statutes.

f. FeLV testing is recommended before vaccination; infected cats do not derive any benefit from vaccination.

g. This product is *not* the same as the *B. bronchiseptica* vaccine approved for use in dogs; the product approved for use in dogs should not be used in cats.

h. This formulation of FIV vaccine is the only one available at the time of this writing.

i. Some FIV vaccines induce antibodies indistinguishable by current tests from those induced by natural infection, and may confound attempts to diagnose infection. Cats should test negative for infection before such vaccines are initially administered.

The United States Department of Agriculture (USDA), under the authority granted by the Virus, Serum, Toxin Act of 1913, requires that vaccines produced for interstate sale be pure, potent, safe, and efficacious. Efficacy, as defined by the USDA, is an in vivo determination of a vaccine's ability to induce an immune response and is usually determined by either direct challenge exposure of test animals (usually 20 to 30 vaccinates and a smaller number of nonvaccinated controls) or by measurement of serologic response. Although such tests are necessary, they provide little information regarding whether the immune response induced by vaccination is clinically relevant. Several reasons exist for these shortcomings: the test animals tend to be of uniform age and lineage, the number used is usually small, the route and dose of challenge agent may not mimic natural exposure, and the virulence and genetic-antigenic diversity of field isolates may be highly variable and differ from the challenge agent. Studies that involve larger numbers of animals of diverse ages, health status, lineage, as well as those that are exposed under natural settings provide additional information, but they are expensive, difficult to control, and uncommonly performed.

164.2 VACCINATION SITES

Standardizing and recording parenteral vaccine sites in the patient's permanent record is important for monitoring local reactions and management of vaccine-associated sarcomas. Parenteral vaccines should not be administered in

the dorsal spinal region or body wall. Limiting administration to the distal limbs provides the best opportunity for control of vaccine-associated sarcomas[4] (Table 164-1).

612

615

164.3 INDIVIDUALIZING VACCINATION PROTOCOLS

The benefits of vaccination are well documented, but harmful effects can result in some individuals. As with any medical procedure, the benefits of vaccine administration should far outweigh any vaccine-associated risks. In deciding whether a particular vaccine antigen should be administered to a particular cat, it is necessary to estimate several patient and vaccine variables. Patients should be evaluated based on their risk of exposure (which requires an understanding of the means of infectious agent transmission) and the expected response to exposure (likelihood of infection if exposed, likelihood and severity of disease if infected). Vaccine variables include the proportion of vaccinates expected to benefit from vaccination, the expected immune response to vaccination (sufficient to prevent infection, sufficient to reduce the severity of disease if infection occurs), and the likelihood and severity of vaccine-associated adverse events. The suggested vaccination protocol outlined in Table 164-1 takes these variables into consideration.

165 CHAPTER • 165 Diseases Caused by Systemic Bacterial Infections

Katrin Hartmann

Craig E. Greene

165.1 LEPTOSPIROSIS

165.1.1 Etiology

Leptospirosis, a zoonotic disease of worldwide significance in many animals and humans, is caused by infection with antigenically distinct serovars of the motile spirochetal bacterium *Leptospira interrogans sensu lato*. The bacterium can persist in wildlife reservoirs, contaminating the environment.[1] *Leptospira* organisms are thin, flexible, filamentous bacteria made up of fine spirals with hook-shaped ends. They are motile through writhing and flexing movements while rotating along their long axis.[2] Confusion may arise about the classification of leptospires because serogrouping used in the past overlaps with newer classifications based on genetic methodologies.

In all surveys of domestic animals, antibody prevalence is greater than clinical illness, suggesting that subclinical infections occur commonly. However, these spirochetes also can cause severe, sometimes fatal, disease. More than 200 different serovars have been identified in the *Leptospira interrogans* complex,[3] although the pathogenic importance of individual isolates is unknown.[4–6] Each serovar has a primary host that maintains the organism and contributes to its dissemination in the environment. Although all mammals are susceptible to infection, clinical signs are most severe with non-host-adapted serovars.[7] Leptospirosis is common in dogs, and its importance in veterinary practice may be underestimated. Reports of leptospirosis in cats are rare.

Canine leptospirosis was first described in 1899. Prior to 1960, serovars *icterohaemorrhagiae* and *canicola* were believed to be responsible for most clinical cases of canine leptospirosis. The disease, caused by acute or subacute hepatic and renal failure, typically was characterized by acute hemorrhagic diathesis, icterus, or uremia.[8] After a bivalent, serovar-specific vaccine against *canicola* and *icterohaemorrhagiae* came into widespread use, the incidence of “classic” leptospirosis in dogs appeared to have decreased.[9] However, these vaccines did not induce immunity against other serovars, leading to a relative increase in the incidence of disease attributed to serovars of other serogroups.

Awareness of leptospirosis has expanded as the range of tested serovars has increased. The serovar *grippotyphosa,* first discovered in kenneled hunting dogs in the southeastern United States, has been identified as a predominant serovar in dogs east of the Mississippi River. In the northeastern states, *pomona* has predominated; on the western coast, *bratislava* and *pomona*. Serogroup *Australis* has been incriminated in an outbreak in Canada and has been documented as the cause of chronic hepatitis in dogs in France. In Germany, the predominant serovars are *grippotyphosa, bratislava, saxkoebing,* and *sejroe;* a recent survey in Italy identified *bratislava* and *grippotyphosa*.[8–16]

165.1.2 Pathogenesis

Leptospires can be transmitted directly between hosts in close contact through urine, venereal routes, placental transfer, bites, or ingestion of infected tissues as the organism penetrates mucosa or broken skin. Shedding by infected animals occurs, usually via urine. The exact duration of shedding and potential spread to other dogs or humans is uncertain and may depend on the serovar. Recovered dogs can excrete organisms in urine intermittently for months to 4 years after infection.[17] Indirect transmission, which happens more often, occurs through exposure of susceptible animals to a contaminated environment (e.g., soil, food, or bedding). Water contact is the most common means of spread, and habitats with stagnant or slow-moving warm water favor organism survival. Leptospires in contaminated water invade the host through skin wounds or through intact mucous membranes. Because optimum survival conditions include a neutral or slightly alkaline pH, the organism survives only transiently in undiluted acidic urine (pH 5.0 to 5.5), whereas dilute urine provides a suitable habitat. Ambient temperatures between 0° and 25° C favor survival and replication, whereas freezing markedly decreases survival. Temperature and pH requirements explain the apparent increased incidence of canine leptospirosis in late summer and early fall, in the southern, semitropical belt of the United States, and in similar climatic regions worldwide. Clustering of cases depends on environmental factors. Seasonality is clearly associated with rainfall,[18–20] and disease outbreaks often occur during or immediately after periods of flooding.

Once in a susceptible host, leptospires begin to multiply as early as 1 day after entering the blood vascular space.[21] They invade many organs, including the kidneys, liver, spleen, central nervous system (CNS), eyes, and genital tract. Leptospires damage organs by replicating and causing inflammation. Initial replication mainly damages the kidneys and liver. The extent of damage to internal organs varies, depending on the virulence of the organism and host susceptibility.[22]

Recovery from infection depends on the production of specific antibodies. As serum antibodies increase, the organism is cleared from most tissues, except for the kidneys. Renal colonization occurs in most infected animals, and the organism usually persists in renal tubular epithelial cells, causing shedding from the kidneys for months to years after clinical recovery. The prognosis is highly dependent on conservation of renal function.

165.1.3 Clinical Signs

Signs of hepatic and renal dysfunction and of coagulation defects usually predominate in dogs with leptospirosis. The severity of clinical signs depends on the age and immunocompetence of the host, the environmental factors affecting the organisms, the serovar involved, and the virulence and quantity of the acquired bacteria. Younger dogs (less than 6 months) are more severely affected and develop more signs of hepatic dysfunction in any disease outbreak.

A majority of leptospiral infections in dogs are subclinical. Peracute leptospiral infections are characterized by massive leptospiremia, causing shock and often death with few premonitory signs. Less severe infections are characterized by fever, anorexia, vomiting, dehydration, increased thirst, and reluctance to move. 616 617

Leptospiral infection can lead to similar clinical signs independent of the etiologic serovar, and reports on different clinical appearances may be more related to geographic distribution. Renal colonization occurs in most infected animals because the organism replicates and persists in renal tubular epithelial cells, even in the presence of neutralizing antibodies. Acute impairment of renal function may result from decreased glomerular filtration caused by swelling that impairs renal perfusion. Progressive deterioration in renal function results in

oliguria or anuria. Renal function in some dogs that survive acute infections may return to normal within several weeks, or chronic compensated polyuric renal failure may develop.

The liver is another major parenchymatous organ damaged during leptospiremia. Profound hepatic dysfunction may occur without major histologic changes because of subcellular damage. The degree of icterus in both canine and human leptospirosis usually corresponds to the severity of hepatic necrosis. In contrast, the icterus, hemoglobinemia, and hemoglobinuria that develop in cattle with leptospirosis result from a specific hemolytic toxin produced by serovar *pomona*. In dogs, icterus is less likely a result of hemolysis because even decreased osmotic fragility has been detected in canine leptospirosis. Chronic active hepatitis and hepatic fibrosis have occasionally been demonstrated as sequelae to serovar *grippotyphosa* infection in dogs. Presumably, the initial hepatocellular injury and the persistence of the organism in the liver result in altered hepatic circulation and immunologic disturbances that perpetuate the chronic inflammatory response. This process may cause extensive hepatic fibrosis, cirrhosis, and failure.

Tissue edema and disseminated intravascular coagulation (DIC) may occur rapidly and result in acute endothelial injury and hemorrhagic manifestations. *Leptospira* lipopolysaccharides stimulate neutrophil adherence and platelet activation, which may be involved in inflammatory and coagulatory abnormalities.

Other body systems may also be damaged during the acute phase of infection. A benign meningitis is produced when leptospires invade the CNS; however, it is not as common as in humans. Uveitis occasionally is present in naturally occurring and experimentally induced canine leptospirosis. Abortion and infertility resulting from transplacental transmission of leptospires associated with serovar *bataviae* infection have been described. Pulmonary manifestations include labored respiration and coughing. Interstitial pneumonia has been documented as the cause in humans, whereas lung changes in dogs with leptospirosis are associated with pulmonary hemorrhage, most likely due to endothelial damage and vasculitis.[23]

Laboratory abnormalities usually include leukocytosis, thrombocytopenia, increased serum urea and creatinine, electrolyte disturbances, bilirubinemia, and increased serum hepatic enzyme activities. Coagulation parameters may be altered in severely affected animals. Urinalysis abnormalities include bilirubinuria, sometimes glucosuria, proteinuria, and increased numbers of granular casts, leukocytes, and erythrocytes in the sediment.

165.1.4 Diagnosis

Establishment of a diagnosis is important, because animals can serve as reservoirs and pose potential zoonotic risks. The diagnosis of leptospirosis can be accomplished by several techniques. Detection of antibodies using the microscopic agglutination test (MAT) is the most common diagnostic method[4,7,24,25]; however, other methods to detect antibodies, such as immunofluorescent assays or enzyme-linked immunosorbent assay (ELISA), have been used. The problem in interpretation of antibody test results is the high prevalence of subclinical infections and the persistence of antibodies. In addition, leptospiral vaccines induce antibodies, therefore the presence of antibodies in itself does not necessarily reflect disease. However, a high MAT titer to a nonvaccinal serovar and no (or only low) titers against vaccinal serovars, accompanied by clinical signs of leptospirosis, must be considered highly suggestive of active infection.[2,4,9] In some cases, cross-reactive results may make identification of the infecting serovar difficult. High titers to a specific serovar may not definitely identify the causative serovar, because shared epitopes among organisms of related serovars frequently induce production of cross-reactive antibodies.[25] Laboratory variation and differences in host-specific humoral immune responses sometime make correct assignment of antibody tests even more difficult.

Another diagnostic criterion is a fourfold increase in MAT titers. Because antibody test results are often negative in the first week of illness, especially in young dogs (less than 6 months of age), a second serum sample should be obtained within l to 2 weeks. Negative initial antibody tests can be explained by the 7 to 9 day period required before MAT antibodies are detected. MAT titers become positive after about l week, peak at 3 to 4 weeks, and remain positive for months after both natural infection and vaccination.[2] Therefore, to confirm current infection versus previous infection or vaccination, a rising titer should be demonstrated. Antimicrobial therapy early in the course of the disease may decrease the magnitude of the titer rise. Lower levels of antibodies to leptospiral antigens used in the MAT may also indicate exposure to infection with nonleptospiral spirochetes (e.g., oral spirochetal infections). However, dogs exposed to ticks harboring *Borrelia burgdorferi* that developed high titers to that organism did not show significant increases in anti-leptospira titers on the MAT. In contrast, leptospiral infections can affect antibody results for borreliosis. An advantage of the MAT is its serovar specificity; however, it cannot distinguish between IgM and IgG antibodies.

Besides the widely used MAT, a combined IgM/IgG ELISA[26–28] or immunofluorescent assay (IFA)[29] can be used to measure leptospiral antibodies. IgM antibodies increase within the first week of infection (before the MAT titer); the maximum IgM titer develops within 14 days and decreases thereafter. IgG antibody tests turn positive 2 to 3 weeks after infection and persist for months, with a maximum titer after l month.[2] A combined IgM/IgG test from a single sample is better suited to distinguishing natural infection from vaccine-induced immunity than is the MAT, because dogs that have been vaccinated and have received booster shots demonstrate a high IgG titer but low or negative IgM antibodies. However, these combined tests cannot distinguish between different serovars.

The organisms can be identified directly by means of several techniques, including visualization in fresh urine by dark-field microscopy or in tissue sections or on air-dried smears by light microscopy as well as by culturing the organism or by detection of deoxyribonucleic acid (DNA) by polymerase chain reaction (PCR). However, all direct methods are reliable only with positive results. A negative result never excludes the presence of the infectious agent. Identification of leptospires in urine by dark-field microscopy[9,24,30] is frequently unrewarding, and both positive and negative results should be followed by culture or antibody testing. Leptospires sometimes can be seen by light microscopy in tissue sections or on air-dried smears with Giemsa stain or silver impregnation. Immunofluorescence and immunohistochemical staining techniques have been adapted to identify *Leptospira* organisms in tissues imprints of liver and kidney and in body fluids such as blood or urine, and these techniques potentially can be used to identify animals shedding organisms in urine when culture is impossible or too time-consuming.[31]

Although culture of the organism from blood, urine,[25] or cerebrospinal fluid[32] would be the ideal method, leptospires are difficult to culture and may take weeks to months to grow. They are fastidious, and sampling should always precede institution of antimicrobial therapy. Dogs are leptospiremic during the first week of infection, but the number of circulating organisms subsequently decreases as serum antibodies increase. Urine (sampled by cystocentesis to avoid overgrowth by normal flora) is the best fluid for culture. If animals are adequately hydrated, administration of a low dose of a diuretic such as furosemide (0.5 mg/kg) just before urine collection may facilitate recovery of organisms. Urine should be alkalinized to pH 8.0 or greater during transport. Special liquid, semisolid, or solid culture media should be used. Definitive differentiation of the etiologic serovar can also be accomplished using culture (if culture is successful).

PCR has been used to detect leptospires in blood, cerebrospinal fluid (CSF), aqueous humor, and urine. Because the concentration of leptospires is highest in urine, urine testing is recommended. PCR techniques for identifying the organisms in urine has been experimentally shown to be sensitive and specific and can help

establish a diagnosis at an early stage of infection. In two studies comparing PCR, culture, and antibody testing in healthy and diseased animals, PCR was significantly more sensitive than the other methods in identifying shedders and diagnosing the disease.[33–35] Because culturing of urine is time-consuming and insensitive, the PCR approach may be most useful for direct detection of the organism. Unfortunately, PCR is not yet widely available. Recent advances in PCR techniques have allowed not only diagnosis of leptospirosis but also identification of specific *Leptospira* serovars.[36]

165.1.5 Treatment

Supportive therapy for animals with leptospirosis depends on the severity of the clinical signs, whether renal or hepatic dysfunction is present, and other complicating factors. Antimicrobial therapy is essential to terminate bacteremia. Treatment is divided into two stages. The goal of the first stage is to immediately inhibit multiplication of the organism and rapidly reduce fatal complications of infection, such as hepatic and renal failure. Penicillin and its derivatives are the antibiotics of choice for terminating leptospiremia. Initially, ampicillin (22 mg/kg given intravenously every 8 hours) or, preferentially, amoxicillin, if available for intravenous (IV) use (22 mg/kg given every 12 hours), can be administered parenterally to a vomiting, uremic, or hepatically compromised animal. These drugs prevent shedding and transmission of the organism within 24 hours of therapy. They do not, however, clear renal infections or eliminate the carrier state and chronic shedding. The goal of the second stage, therefore, is to eliminate the carrier state through administration of drugs such as tetracyclines, aminoglycosides, or the newer erythromycin derivatives. Doxycycline (5 mg/kg given orally every 12 hours for 3 weeks) is the drug of choice. Doxycycline treatment should start as soon as oral therapy is possible and liver function is uncompromised. Doxycycline is usually given orally because IV administration can cause shock and vomiting, and subcutaneous injection leads to abscessation. Oral administration, however, can cause gastrointestinal side effects. Doxycycline can be given regardless of the degree of renal dysfunction, whereas aminoglycosides must be strictly avoided if any degree of renal dysfunction is present. The doxycycline dose does not need to be adjusted in animals with renal failure because it is predominantly excreted in the feces. However, doxycycline can lead to liver toxicity. It should be started only after the animal stops vomiting and liver enzyme values have returned to the reference range. In animals with only mild clinical signs, doxycycline can be used for both initial and elimination therapy.

The extent of renal damage after treatment determines the overall prognosis for affected dogs. Some dogs have an apparent clinical recovery after treatment, whereas others develop persistent azotemia.

165.1.6 Prevention

Inactivated bacterins against *icterohaemorrhagiae* and *canicola* infection have been widely used, and this strategy has reduced the prevalence of highly virulent forms of illness. However, these vaccines are not cross-protective against the serovars responsible for most of the current infections in dogs. A recently developed bacterin vaccine that contains *grippotyphosa* and *pomona* strains, either as bivalent or quadrivalent products with the other two strains (Duramune LGP or Duramune LCI-GP, respectively; Fort Dodge Animal Health, Fort Dodge Iowa), is now on the market in the United States. The use of multistrain vaccines likely will reduce disease prevalence.[37] Because the highest titers are produced by multiple injections, yearly (and eventually biannual) vaccinations should be given to dogs in endemic areas, and all dogs should receive at least three injections in the primary vaccination series. IgG titers, which are primarily responsible for protection in dogs, are produced for at least l year after the third vaccination.

Debate has arisen over the necessity of routine vaccination in dogs. As inactivated bacterins, leptospiral vaccines have caused allergenic reactions, especially when combined with other adjuvanted agents. However, many manufacturers have improved and purified their leptospiral vaccines, producing safer multicomponent products. A number of these newer vaccines have been shown to protect against challenge for at least 1 year and to prevent the development of a carrier state in many vaccinated animals.[2] *Icterohaemorrhagiae* and *canicola* infections continue to occur in unvaccinated animals, which indicates that these agents have not been eradicated.

Doxycycline has been given at a low dose (200 mg once weekly) to humans in endemic areas for prophylaxis when vaccination with appropriate serovar bacterins is unavailable. Such therapy may result in the development of bacterial resistance and is not recommended for dogs (or humans).

Wild animal reservoirs and subclinically affected domestic animals continue to harbor and shed organisms. Therefore control of rodents in kennels, maintenance of environmental conditions to discourage bacterial survival, and isolation of infected animals are important steps in preventing the spread of disease. Control of shedding by wild animal reservoirs is impossible. For these reasons, vaccination of dogs is essential.

165.1.7 Leptospirosis in Cats

The prevalence of clinical illness is low in cats, despite the presence of leptospiral antibodies in the feline population and the exposure of cats to leptospires excreted by wildlife. Serovars *canicola, grippotyphosa*, and *pomona* have been isolated from cats. Outdoor cats have the highest antibody prevalence, and transmission from rodents is suspected. Cats may also be exposed to the urine of cohabiting dogs. Although cats develop antibodies after exposure, they appear to be less susceptible than dogs to both spontaneous and experimental infection. Clinical signs are usually mild or not apparent in feline leptospirosis, despite the presence of leptospiremia and leptospiuria and histologic evidence of renal and hepatic inflammation. The lack of clinical cases may be related partly to cats' aversion to water and partly to natural resistance to infection.

165.1.8 Public Health Considerations

The majority of leptospiral infections in humans are identified among those involved in water-related activities, either through work or leisure activities. In some outbreaks, simultaneous exposure of humans and dogs occurs. 618
Urine from infected dogs can cause disease in humans when it comes in contact with mucosal surfaces or a 619
break in the epidermal barrier. Latex gloves are necessary when urine or urine-contaminated items are handled, and face masks and goggles should be worn when contaminated kennel areas are hosed down.
Urine-contaminated areas should be cleaned with dry paper first (to avoid dilution of urine), then washed with detergent and treated with iodophor disinfectants, to which the organism is susceptible. All dogs known to be or suspected of shedding should be treated with doxycycline.

165.2 BORRELIOSIS

165.2.1 Etiology

Tick-borne spirochetoses are a group of diseases that affect humans and animals worldwide. They can be divided into the Lyme disease group (Lyme borreliosis), which is transmitted by *Ixodes* ticks, and the relapsing fever group, which is transmitted by soft ticks. The Lyme disease group was recognized more recently and is

now the most commonly diagnosed vector-borne disease in humans.[1] Borreliosis has been known in Europe since the early 1900s; Alan Steere of Yale University first described the disease and the connection to tick bites after a 1975 outbreak in Lyme, Connecticut (which led to the name *Lyme disease*). However, evidence suggests that this infection in indigenous wildlife and their tick vectors is much older. Studies have demonstrated that ear skin samples from museum specimens of white-footed mice collected near Dennis, Massachusetts, in 1894 contained *Borrelia* DNA.[38] *Borrelia* organisms also were detected in British ticks from 1897.[39] Lyme disease now has been reported in North America, Europe, and Asia, with unconfirmed cases in Australia, South America, and Africa. Experimentally induced and naturally occurring Lyme borreliosis has been described in dogs, cats, and other domestic animals.[40] Antibody prevalence in dogs in endemic areas correlates with living in forested and urban areas and time spent outdoors.[41] In some endemic areas (e.g., Southern Germany), about 30% of ticks are infected,[42,43] and approximately 95% of dogs have antibodies indicating exposure.

Lyme disease is caused by *Borrelia burgdorferi sensu lato,* which comprises several species that affect humans and dogs worldwide. Like most spirochetes, *Borrelia* organisms are small, corkscrew-shaped, motile, microaerophilic bacteria of the order Spirochaetales that can move in connective tissue using their flagella. At least six species have been found in dogs and humans. *B. burgdorferi sensu stricto* predominates in humans and dogs in the United States. It also is found in Europe but only in about 10% of isolates. *B. garinii* and *B. afzelii* are the most common species in Europe. *B. japonica* has been isolated from ticks on humans and dogs in Japan. Recently, two new species (*B. lusitaniae* and *B. valaisiana*) have been detected. In cats, the natural disease is poorly documented, although cats can be infected experimentally. Cats seem to be less susceptible to clinical signs than dogs, and dogs less susceptible than humans.

The presence of disease and its clinical features depend on the isolate in a given geographic region. Genetic variability of isolates also occurs within each continent. In humans, different species are clearly associated with different tissue tropism and clinical problems; this is also likely in dogs. In humans, *B. burgdorferi sensu stricto* infection is associated with annular skin lesions, polyarthritis, and meningitis. Meningopolyneuritis (Bannwarth's syndrome) is the primary clinical sign in humans with *B. garinii* infection in Europe, whereas *B. afzelii* infection has been associated with chronic arthritis and dermatitis *(erythema chronicum migrans)*.[44]

165.2.2 Pathogenesis

Unlike *Leptospira* spp., *Borrelia* organisms do not survive free living in the environment. They are host associated and are transmitted between vertebrate reservoir hosts and hematophagous arthropod vectors. The principal vectors of *B. burgdorferi sensu lato* are various species of hard ticks of the *Ixodes* complex. *I. ricinus* and *I. persulcatus* are the primary vectors in Europe and Asia, respectively. In the United States, the closely related black-legged ticks *I. scapularis* (Northeast, Midwest, and Southeast) and *I. pacificus* (West) are the main vectors. These small *Ixodes* ticks (less than 3 mm) generally feed on more than one host during their life cycle. *I. scapularis* is a three-host tick with a 2-year life cycle. Infected nymphs overwinter, and in the spring they transmit infection to reservoir hosts, which in turn infect feeding larvae. Larvae and nymphs feed primarily on rodents and small mammals (northern *I. scapularis*) and reptiles (southern *I. scapularis*), whereas adult ticks feed on deer or larger mammals. Humans and pets are usually infected by nymphs or adult ticks. Because reptiles are not competent reservoir hosts, the infection rate of southern *I. scapularis* ticks is much lower than that of northern *I. scapularis* ticks. Furthermore, because the southern *I. scapularis* ticks do not always feed on mammals, the prevalence of *Borrelia* infection is relatively low in the southern regions.[40] Other ticks and insect vectors have been found to harbor *Borrelia* organisms but do not seem to maintain infection or to be important for transmission. Direct transmission of *Borrelia* spirochetes between reservoir hosts is unlikely, as is transovarial transmission in ticks. Canine urine is also an unlikely source of spread. In a natural infection

model, control dogs in direct contact with infected dogs for up to l year did not develop antibodies, and organisms could not be isolated from the urine of infected dogs. These studies also did not document any evidence of *in utero* spread.[45] However, *Borrelia* organisms can survive freezing and storage, which makes artificial insemination a potential source of infection.[46] Blood transfusions offer another potential source of infection.

Natural spirochete transmission requires 48 hours of tick attachment, during which time organisms multiply and cross gut epithelium into the hemolymph, disseminate to the salivary glands, and infect the host through tick saliva.[47] Once in the body, *Borrelia* spirochetes usually cause persistent infection. Experimental evidence suggests that *Borrelia* organisms exist extracellularly and, in an undetermined way, can evade immune clearance. Organisms can persist and proliferate for extended periods (probably lifelong in most animals) in intercellular spaces in the skin at the site of the tick bite. Most infected animals never develop clinical signs. In dogs that do not develop clinical signs, it is likely that *Borrelia* organisms persist but do not invade connective tissues and therefore do not cause clinical signs but do cause persistent antibody response. In very few animals, *Borrelia* organisms proliferate and migrate from the skin at the site of the tick bite through connective tissues, including joints, beginning in close proximity to the tick bite. Clinical illness in these dogs results from the host's inflammatory response to their presence and migration. Despite treatment for months or years, *Borrelia* spirochetes can persist in the skin, connective tissues, joints, and nervous system and be detected by PCR or sometimes by culture of blood, cerebrospinal fluid, or urine.

It is still not known why a specific animal or human being develops clinical signs. Pathogenicity depends on the *Borrelia* species, and *B. burgdorferi sensu stricto* seems to be more pathogenic in dogs than the species mainly found in Europe. Evidence suggests that about 5% to 10% of dogs with antibodies in endemic areas in the United States develop clinical disease within 2 to 5 months of infection[48]; the percentage is much lower in endemic areas in northern Europe. Experimental studies have shown that the number of infected ticks that feed is critical. The age and immune status of the animal also seem to be important. Treatment with high doses of glucocorticoids at the time of infection has been shown to increase the likelihood of clinical signs. The development of immune complications, such as arthritis, is probably related to host immunodeficiency. Humans with certain haplotypes of the major histocompatibility complex are prone to more severe clinical manifestations of the disease.[49]

619 620

165.2.3 Clinical Signs

All experimental infections in dogs have used *B. burgdorferi sensu stricto* strains, therefore the clinical condition caused by this organism is relatively well described. In experimentally infected dogs, clinical illness begins 2 to 5 months after tick exposure. Clinical signs include fever, inappetence, lethargy, lymphadenopathy, and episodic shifting limb lameness related to polyarthritis. Arthritis starts first in the joint that is closest to the tick bite. It has been shown that the release of proinflammatory cytokines and especially interleukin-8 (IL-8) plays an important role in the pathogenesis of acute arthritis.[50,51] Despite the transient nature of the arthritis, pathologic changes in the joints are progressive. Chronic nonerosive polyarthritis is the primary condition after prolonged infection, and it may persist despite antimicrobial therapy.

The clinical signs that develop in natural infection or in infections caused by other *Borrelia* species have been less definitively characterized. Glomerulonephritis and protein-losing glomerulopathy progressing to renal failure have been described in naturally infected dogs.[52,53] An acute, progressive renal failure associated with azotemia, uremia, proteinuria, peripheral edema, and body cavity effusions has been described in 49 dogs with positive antibody test results from *Borrelia*-endemic areas. Labradors and golden retrievers were commonly

affected.[54] In Europe, glomerulonephritis is often found in Bernese Mountain dogs with high antibody titers to *Borrelia* organisms. *Borrelia* organisms are likely involved, but not yet proven, in this rapidly progressing glomerular disease. A dermatologic lesion of expanding erythema around the site of the tick bite has not been well documented in affected dogs. A small, reddened lesion, not as dramatic as the erythema migrans seen in humans, can be seen but disappears within the first week. However, the organism can be isolated from the skin area for an extended period. Neurologic manifestations caused by meningitis or encephalitis have not been well documented in either experimental or natural canine infection. Another nonarthritic syndrome that has been reported is cardiac arrhythmia from myocarditis, similar to that reported in humans.

No specific hematologic or biochemical changes are associated with Lyme disease. In contrast to leptospirosis, leukocytosis is not seen, probably because *Borrelia* organisms rarely spread hematogenously, but rather through connective tissue. Dogs with renal manifestation may have proteinuria due to glomerulonephritis sometimes secondary azotemia, hematuria, pyuria, and tubular casts. Synovial fluid analysis findings are typical for a suppurative polyarthritis, with leukocyte counts ranging from 2000 to 100,000 nucleated cells per microliter.

165.2.4 Diagnosis

Lyme borreliosis is likely overdiagnosed in human and veterinary medicine because it has become a “trendy” illness. Overestimation results from antibody cross-reactivity to other infectious agents, from the inaccuracies of antibody tests, and from the predominance of asymptomatic infections. The presence of antibodies to *Borrelia* organisms signifies exposure to a spirochete but does not prove that current clinical illness is caused by *Borrelia*. In endemic areas, most animals in the population have antibodies without ever developing clinical signs.

Various problems have been noted with antibody testing. First, no standardization exists for antigen preparations, techniques, and interpretation by different laboratories. Matched sera sent to 10 commercial laboratories for antibody testing found only 53% agreement.[55] Antibody screening procedures available for animals are ELISA and IFA techniques, usually using whole cells that contain many cross-reactive proteins to other bacteria, especially other spirochetes. In humans it has been shown that other inflammatory conditions, such as autoimmune diseases, rheumatoid arthritis, syphilis, and periodontal disease, can produce positive results.[2] *Leptospira*-positive canine sera also can have low levels of reactivity to *B. burgdorferi* in ELISA and IFA. In Great Britain, dogs with periodontal disease and presumed oral spirochetosis showed a higher level of antibodies against *B. burgdorferi* than healthy dogs from the same hospital population.[56] Some of the reports of human and animal Lyme disease in the western United States may actually be related to relapsing fever and the nonspecificity of whole-cell ELISA or IFA. Dogs vaccinated against borreliosis show antibodies in whole-cell ELISA and IFA for months to years after vaccination.

Paired titers are not helpful in the diagnosis of Lyme disease because high antibody titers usually persist for a long period. Simultaneous measurement of IgG and IgM in a single specimen theoretically would provide more information in other diseases. However, in naturally *Borrelia*-infected dogs and humans, IgM persists for many months, therefore a positive IgM titer does not help to confirm recent exposure or infection.[57,58]

False-negative antibody test results are rare. Early antibody tests are usually negative because the immune response to *B. burgdorferi* develops gradually. Experimentally infected dogs have ELISA-positive results by 4 to 6 weeks after exposure. Titers were at their highest levels by 3 months after exposure. Titer increases almost always precede clinical lameness and fever in experimentally infected dogs,[45] therefore a negative titer in an animal with clinical signs rules out Lyme disease with a high probability.

Because the routine antibody tests (ELISA and IFA) are nonspecific and because neither testing of paired samples nor IgM/IgG differentiation is useful, other confirmatory tests must be performed, such as the Western blot assay or the new C6 ELISA. These tests, which have higher specificity and sensitivity than whole-cell ELISA or IFA, can be used to detect antibodies that specifically indicate infection with *B. burgdorferi* and to exclude vaccination or contact with other bacteria. Western blot assays detect a spectrum of antibodies, and the pattern of antibody reactivity after natural infection differs from that produced after vaccination. After natural exposure to *B. burgdorferi,* antibodies develop to several proteins, including outer surface proteins. One of these outer surface proteins, OspC, appears to be expressed by *Borrelia* organisms in the host at warmer temperatures but is lost at lower temperatures in the tick or with *in vitro* cultivation. However, OspC is a prominent protein response to infection, and high amounts of anti-OspC antibodies are produced after natural infection. In contrast, the protein OspA is mainly expressed by *Borrelia* during the arthropod state (or if cultured *in vitro*). Therefore reactivity to OspA but not OspC occurs in vaccinated dogs (because the vaccine strains are cultured *in vitro*) but is lacking in naturally infected dogs. This effect is even more prominent if recombinant vaccines containing OspA are used rather than whole *Borrelia*. Thus the Western blot antibody pattern expressed by vaccinated dogs differs from that of naturally infected dogs.[59,60]

Newer ELISA tests that incorporate OspC also help differentiate between natural infection and vaccination.[61] Recently the antigenic properties of a 26 amino acid–long invariable region located within the central domain of the VlsE molecule, the variable surface of *B. burgdorferi,* were investigated. This region, named *IR* (invariable region) *6,* was determined to be antigenetically conserved among strains of the *B. burgdorferi sensu lato* complex and to be immunodominant in both human and canine hosts.[62] A new, in-house ELISA (C6 ELISA), designed using the IR6 sequence as a peptide (C6) biotinylated at the N-terminus, recently became available in the United States (SNAP 3Dx; IDEXX, Portland, Maine). The anti-C6 antibody response is highly specific for *B. burgdorferi* and is more sensitive than whole-cell tests in early infection, detecting antibodies as early as 3 weeks post exposure.[63] It also is more sensitive in detecting *Borrelia* infection in Europe than other commercial ELISA kits.[64] Dogs with leptospirosis, Rocky Mountain spotted fever, babesiosis, ehrlichiosis, and heartworm disease do not have antibodies to C6. Furthermore, C6 is not affected by the currently available Lyme vaccines.[65] C6 antibody levels also seem to correlate to *Borrelia* loads, dropping rapidly after treatment with antibiotics,[66] whereas conventional ELISA results stay at medium levels for a long time even after successful treatment.[67] Although already used in veterinary practice in endemic areas,[68] the C6 ELISA has not been validated in controlled studies. It must be considered that both the Western blot assay and the C6 ELISA, although more specific, only indicate natural exposure to *B. burgdorferi* and do not predict clinical disease.

620 621

In humans, CSF antibody titers have been compared with serum antibody titers in an attempt to diagnose neuroborreliosis. Intrathecal production of specific antibodies to *B. burgdorferi* can be demonstrated if the ratio of CSF to serum *B. burgdorferi* antibodies is greater than the CSF to serum concentration of albumin, total IgG, or specific IgG against another infectious agent. An increased intrathecal antibody concentration was demonstrated in dogs with neurologic dysfunction. The results of such reports are difficult to assess because the dogs were from endemic areas, and no supporting histopathology or culture findings were supplied.[40]

Culture of spirochetes from specimens of a diseased patient is the most definitive means of diagnosis but in most cases is difficult due to the low number of organisms present and the insensitivity of isolation methods. Special media (e.g., modified Barbour-Stoenner-Kelley medium) are required, but even then culturing is insensitive.[69] Skin appears to be the most consistent tissue for premortem or postmortem culture when specimens are taken at or near the site of tick attachment.[67] Xenodiagnosis, in which uninfected ticks become

infected after feeding on suspect infected hosts, has proved reliable in a research laboratory setting but is too time-consuming and is not useful for routine clinical diagnosis.

PCR is highly specific. The best materials for diagnosis are skin samples, which should be taken at a location closest to the tick bite. If the tick bite location is unknown, a sample should be taken close to the joint in which the first lameness or swelling was observed. If no arthritis is or was present, the sample should be taken from an area that is generally most exposed to ticks (usually the front part of the dog). PCR can also be performed using urine,[70] which is slightly less sensitive. Blood is not useful, because *Borrelia* organisms rarely spread hematogenously. Joint fluid,[71] synovia samples, or CSF samples are excellent PCR material if clinical signs are present. PCR cannot distinguish between live and dead organisms. Research has shown that small DNA fragments of *Borrelia* may persist in synovial membranes after treatment,[67,72] and these fragments may induce positive PCR results. However, experimentally injected *Borrelia* DNA (without replicating *Borrelia*) was destroyed and was not detectable after 3 weeks. The sensitivity of PCR is high, but the sample must contain *B. burgdorferi* DNA. A negative PCR result, therefore, never excludes the presence of the organism elsewhere in the body.

165.2.5 Treatment

Because of the difficulty involved in obtaining an accurate diagnosis, antibiotics often are given empirically in an attempt to make a therapeutic diagnosis. Many reports exist of successful recovery after institution of antimicrobial therapy in dogs "diagnosed" with Lyme arthritis. However, clinical improvement after any therapeutic intervention should be viewed with caution, because acute limb and joint dysfunction is intermittent and often resolves after several days to weeks, regardless of whether antibiotics are given.[73] Doxycycline, the drug of choice, by itself has been shown to be chondroprotective in noninfectious arthritis in dogs[74] and thus leads to improvement also in arthritis not related to Lyme disease.

The antibiotics that are most effective for treating *Borrelia* infection are the tetracyclines, ampicillin or amoxicillin, some third-generation intravenous cephalosporins, and erythromycin and its derivatives. Doxycycline (10 mg/kg given orally every 12 hours for 30 days) is the first choice because it is a lipid-soluble tetracycline of relatively low cost. The other drugs are usually reserved for refractory or chronic infections. Improvement often occurs within 24 to 48 hours of initiation of antimicrobial therapy. The greatest success is achieved in the initial phases of clinical illness.

Research suggests that the organism is difficult to eliminate from animals with established infection and that relapses occur despite seemingly adequate treatment regimens.[73,75] Most treatment is instituted for a minimum of 30 days. However, on the basis of research studies, clearance of the organism after 30 days of treatment is questionable. Relapse can occur and PCR results can become positive after discontinuation of antimicrobials.[76,77] Also, inflammatory changes that occur in various tissues, such as the joints, may become self-perpetuating. Intra-articular persistence of *Borrelia* organisms may stimulate chronic immune and inflammatory processes. Animals with more chronic borreliosis are less likely to show improvement or to have relapses, even if treatment is continued for weeks to months. The current recommendations for treating chronic borreliosis are to repeat the 30-day anti-biotic treatment four or five times in 3-month intervals. The *Borrelia* organisms may possibly be eliminated after years of such therapy.[77]

Nonsteroidal anti-inflammatory drugs may be helpful for pain relief during episodes of recurrent arthritis. Immunosuppressive doses of glucocorticoids definitely should be avoided, because immunosuppression may

potentiate infection exacerbation.[76] Tick-exposed dogs that had recovered from clinical signs of Lyme disease and that were treated with oral prednisolone for a 2-week period 16 months after original exposure again demonstrated lameness and polyarthritis.[78]

165.2.6 Prevention

In United States, whole-cell bacterins and recombinant protein OspA vaccines for dogs are commercially available. Whole-cell bacterin vaccines should be avoided, because it is generally undesirable to have multiple components in a vaccine that are not involved in protection from infection and that have the potential to induce a delayed adverse response. Hamsters immunized with whole-cell bacterins and challenged by infected ticks developed arthritis several weeks to months later.[79] This concern has precluded development of a whole-cell bacterin from consideration as a human vaccine. All human vaccines that had been sold in the United States were based on recombinant DNA production of Osp products, but even they have been removed from the market. In Europe and other geographic areas, only whole-cell bacterins are available for dogs (and no vaccines are available for humans) because the multiplicity of infecting strains makes the development of a recombinant product that would protect against the different *Borrelia* species difficult. Multiplicity of infecting strains also makes questionable the protection induced by whole-cell vaccines (which are now on the market in Europe containing *B. burgdorferi sensu stricto* stains), because cross-protectivity between *B. burgdorferi* species could not be demonstrated.

621

622

The advantage of recombinant protein OspA vaccines is that they induce antibodies only to OspA, the protein that is expressed in the tick and not in the dog. Vertebrate hosts infected by *Borrelia* organisms through tick bites rarely develop antibodies to OspA. OspA is expressed by *Borrelia* in unfed ticks but is changed to OspC during transmission from the vector due to the warm conditions during feeding on the vertebrate host. During feeding, antibodies against OspA that are present in the vertebrate's blood due to vaccination enter the tick and neutralize *Borrelia* before the organism enters the host. Antibodies to OspA from the host cause an arrest of growth and salivary gland invasion in the ticks.[80] Spirochetes either are killed instantly by antibody-induced complement lysis or their mobility is reduced such that they cannot continue their migration to the salivary glands of the ticks.[81] In the vaccinated host, only OspA antibodies are present, and these cannot bind to *Borrelia* organisms expressing OspC. Thus the risk of the development of immune complex diseases is reduced compared with whole-cell *Borrelia* vaccines.

The disadvantage of vaccination in general is that the induced antibodies cause positive results on routine antibody testing for months to years. Western blot or C6 ELISA testing must be performed to distinguish vaccine induced from natural exposure antibodies. An additional disadvantage of the vaccine is the possibility that a hypersensitivity reaction may occur if the vaccine is given to a dog harboring the organism.[82] Vaccination of an already infected animal does not clear infection or prevent clinical illness. Local and systemic allergic reactions have been noted with whole-cell vaccines.[83] Vaccines might also be subject to breaks in protection in the future because *Borrelia* organisms are known to change their genotypic and phenotypic makeup, allowing survival despite organism-specific antibodies.

Vector control using residual insecticides or growth regulators is a supportive measure that can help reduce the prevalence of infection in humans and pets. Amitraz-impregnated collars may reduce transmission of *Borrelia* spirochetes in dogs.[84]

165.2.7 Borreliosis in Cats

Cats have been found to be antibody positive for *Borrelia*, and experimental infection has been produced, but naturally acquired disease has not been documented. Approximately 13% of cats tested in the United States had antibodies; however, there was no difference in positive results from cats with or without lameness.[40] In the United Kingdom, 4% of tested cats had antibodies.[85] Cats may be more resistant than dogs to the development of clinical signs. However, when cats were inoculated experimentally with organisms directly from arthropods, they developed multiple limb lameness and had joint, pulmonary, lymphoid, and CNS inflammation at necropsy. Arthritis and meningitis predominated.

165.2.8 Public Health Considerations

There is no evidence that infected pet dogs or cats pose a direct risk to humans except by introducing unfed tick stages into a household. The ticks do not survive long indoors and, if fed, tick stages do not reattach without moulting. However, partly fed ticks can refeed and can pose a greater risk of infection because of the shorter required period of attachment. Direct horizontal spread from dogs and cats to humans is unlikely. It has been speculated that urine from infected dogs could be a source of human infection. *Borrelia* organisms, however, deteriorate quickly in urine, and there is no evidence that human infections have occurred after contact with infected dogs.[86] In addition, in a recent study in the Netherlands, no positive correlation was observed between antibody prevalence in hunters compared with their dogs.[87] Although Lyme disease is classified as a zoonosis, dogs, cats, and humans are incidental hosts for a sylvan cycle that exists in nature. Lyme borreliosis in humans is usually associated with outdoor activities that result in exposure to tick vectors.

165.3 MYCOBACTERIOSIS

165.3.1 Etiology and Pathogenesis

Mycobacteriosis is caused by bacteria belonging to the genus *Mycobacterium,* family Mycobacteriaceae, order Actinomycetales.[40] Mycobacterioses are becoming increasingly important in dogs and cats (partly due to the increase in mycobacterial infections in humans and partly due to improved diagnostic methods), and their importance in veterinary medicine is probably underestimated. These diseases are more common in cats than dogs. In dogs and cats, mycobacteriosis can be divided into three groups, classic tuberculosis (tuberculous form),[88] opportunistic mycobacteriosis (opportunistic form),[89] and feline leprosy (lepromatous form).[90] All three groups can cause cutaneous signs (typically skin nodules with draining tracts and/or ulceration), but mycobacteria of the classic tuberculosis complex can also cause systemic disease. Classic tuberculosis can be caused by *Mycobacterium tuberculosis, M. bovis, M. avium, M. microti, M. microti*-like, and *M. simiae*. Opportunistic mycobacteria recognized as causes of disease in dogs and cats include *M. fortuitum, M. chelonae, M. smegmatis, M. phlei, M. thermosresistibile, M. terrae, M. genavense,* and *M. xenopi*. Feline leprosy is caused by *M. lepraemurium*.

Mycobacterium is a genus comprising morphologically similar, aerobic, environmentally resistant, non-spore-forming, acid-fast, gram-positive bacteria. Mycobacteria have the distinctive property of retaining hot carbolfuchsin and other stains after subsequent treatment with acid or alcohol, a property that facilitates diagnosis. This acid-alcohol fastness is due to the high lipid content of mycolic acid in the cell wall. Mycobacteria are more resistant to heat, pH change, and routine disinfection than other non-spore-forming

bacteria. Most mycobacteria are found in habitats such as water or soil; however, a few can act as pathogens in animals and humans. They have a wide host affinity and pathogenic potential, and with their structural properties and ability to survive intracellularly, they produce granulomatous inflammation.

Classic tuberculosis has become increasingly important[89] in immunosuppressed individuals since the detection of the human immunodeficiency virus (HIV), and it has been caused by more resistant forms of mycobacteria. *M. tuberculosis, M. bovis, M. africanum,* and *M. microti* can cause the disease in humans. Currently, tuberculosis is the leading infectious cause of death in humans, and one third of the world's population is thought to be infected. However, only 10% of immunocompetent individuals develop active disease in their lifetime; the other 90% neither become ill nor transmit the organism. *M. tuberculosis* is the major cause of tuberculosis in humans, and humans are the only reservoir hosts. The inter-related factors of homelessness, illicit drug use, and HIV infection have resulted in an increased prevalence. Multiple-drug-resistant *M. tuberculosis* has emerged in these populations because of irregular compliance with drug therapy.

In dogs and cats, classic tuberculosis can be caused *M. tuberculosis, M. bovis, M. avium, M. microti, M. microti*-like, and *M. simiae*. Although *M. tuberculosis* can cause tuberculosis in dogs and cats,[91,92] it more commonly infects dogs. Dogs and cats are usually infected through direct contact with infected humans, and a canine or feline infection is considered an inverse zoonosis.[93] *M. tuberculosis* has an affinity for tissues with high oxygen content, which explains its common localization in the lungs. Animals with tuberculous pneumonitis discharge organisms in the sputum, as do infected humans, and aerosolized droplets are the primary means of transmission of this disease. To be maintained in nature, *M. tuberculosis* requires infection of reservoir mammalian hosts, because environmental survival is limited to a maximum of l to 2 weeks. Although pets acquire the infection from humans and spread from dogs or cats to humans has not been reported, infected animals are a potential risk to humans, and euthanasia should be considered.

622

623

M. bovis is closely related to *M. tuberculosis* and difficult to distinguish except by biochemical tests and nucleic acid probes. Like *M. tuberculosis, M. bovis* does not exist long in the environment (4 days in summer, less than 28 days in winter), and reservoir hosts are essential for survival of the organism. *M. bovis* is the pathogen of classic “feline tuberculosis.”[94] Cats are more commonly infected with *M. bovis* than dogs, and on an experimental basis, cats appear to be more susceptible to *M. bovis* than to *M. tuberculosis*. Dogs and cats are usually infected by means of unpasteurized milk, uncooked meat, or offal from infected cattle. Clinical disease, therefore, commonly involves the intestines. In areas in which bovine tuberculosis is well controlled, *M. bovis* infections have become extremely rare. In countries such as New Zealand, however, where *M. bovis* has become established in the wildlife population, domestic animals continue to become infected. Dogs and cats may be involved in the maintenance of *M. bovis* on farms, where it is enzootic, and may be responsible for transmission of *M. bovis* to humans. Orally infected dogs and cats usually excrete the organism through feces.

M. avium is a saprophytic organism that has been recognized in recent years as causing infection, especially in cats.[95–101] Poultry and swine are primarily susceptible to *M. avium* infection after contact with infected food or water. Dogs and cats seem to have innate resistance, but exposure is much greater than to *M. tuberculosis* and *M. bovis* because *M. avium* is ubiquitous in the environment. Certain breeds (e.g., Siamese cats[96] and basset hounds) seem to be more susceptible. Immunosuppression seems to play a role, and one case in a cat after renal transplantation has been described.[101] *M. avium* organisms are present in acidic conditions (pH 5.0 to 5.5) and in soils high in organic matter (e.g., acidic swamp areas, coastal plains, and brackish coastal waters). Unlike *M. tuberculosis* and *M. bovis*, *M. avium* organisms remain viable for at least 2 years in the environment. The feces of infected birds contain large numbers of *M. avium,* and infection of dogs and cats occurs from ingestion of infected meat or contact with infected soil contaminated by poultry carcasses or feces. There is no evidence of

spread of *M. avium* between or within animals and humans. *M. avium* can cause disease in immunocompromised humans, but infection usually occurs through exposure to contaminated soil.

M. microti is a rodent pathogen that in earlier literature was reported to infect cats. A few cases in the Netherlands have been described in which hunting cats became infected.[102–104] *M. microti*-like is a new variant that has been identified as a common cause of tuberculosis in cats in Great Britain. It was predominantly found in rural cats with avid hunting behavior. and the source of infection is thought to be a prey species.[105,106]

M. simiae was recently found in an 8-year-old domestic short-hair cat with disseminated mycobacterial disease involving the skin, lungs, lymph nodes, and one eye. *M. simiae* is known to cause pulmonary, cutaneous, or disseminated infection in humans infection with HIV but has not been encountered as a pathogen in companion animals.[107]

Opportunistic mycobacteria that cause disease in companion animals include *M. fortuitum, M. chelonae, M. smegmatis, M. phlei, M. thermosresistibile, M. terrae, M. genavense*, and *M. xenopi*.[108–121] These saprophytic, nontuberculous, nonlepromatous, opportunistic species, also called *atypical mycobacteria,* are ubiquitous in nature, especially in water and wet soil, and are not pathogenic for animals under normal circumstances. Opportunistic mycobacteriosis appears to be more common in tropical and subtropical areas of the world; however, difficulties associated with diagnosis may underestimate the true prevalence. Cats are more often affected than dogs, and adult cats with a hunting or fishing lifestyle are more likely to be affected. Animal-to-animal transmission does not generally occur, and there is little zoonotic risk. Most opportunistic mycobacteria that infect dogs and cats are acquired from the environment after trauma to the skin or soft tissues (puncture or fight wounds) and cause localized tissue reactions in the skin (granulomas and abscesses) or deeper tissues. These organisms are particularly pathogenic if directly inoculated into adipose tissue. Entry through either the gastrointestinal or respiratory tracts is extremely rare. Although systemic immunosuppression has not always been apparent, *M. genavense* infection in a cat infected with the feline immunodeficiency virus (FIV) has been reported.[119]

Opportunistic mycobacteria can be characterized as slow-growing or fast-growing species. Fast-growing *M. fortuitum, M. chelonae, M. smegmatis, M. phlei,* and *M. thermosresistibile* are the species commonly isolated from cats and sometimes dogs with cutaneous lesions in the United States and Australia. Although the slow-growing opportunistic mycobacteria are responsible for several well-characterized cutaneous diseases in humans, they are less commonly isolated from dogs and cats, possibly because of the lengthy time needed for culture. However, the slow-growing species *M. terrae, M. genavense,* and *M. xenopi* have now been described in cats.

Feline leprosy, a disease seen only in cats and not in dogs or humans, is caused by *M. lepraemurium,* the agent of rat leprosy, and is usually introduced via bite wounds from rodents (possibly as soil contaminant) or contact with infected rats. There is no zoonotic risk. The disease is seen most in areas with a temperate maritime climate. Occurrence in cats has been confined to seaport cities of the western United States, New Zealand, Great Britain, Australia, and the Netherlands, with a greater incidence in winter. The organism cannot be cultivated by routine mycobacterial culture methods and requires special media. Feline leprosy is mainly a cutaneous syndrome; regional lymphadenopathy may be present, but systemic disease is rare. FIV or feline leukemia virus (FeLV) infection may play a role in the pathogenesis and predispose to septemic disease. Although the disease is more common in young cats, a clinical syndrome has been described in older cats in which disease progression was prolonged, typically taking months to years, and skin nodules did not ulcerate. This clinical picture was attributed to a *Mycobacterium* species closely related but slightly genetically different from *M. lepraemurium*.[122] In contrast to tuberculous and opportunistic mycobacterial infections, the prognosis

in feline leprosy is good after surgical removal of the cutaneous lesion. Spontaneous resolution of lesions does occur.

165.3.2 Clinical Signs

Infection with tuberculosis-causing mycobacteria in dogs and cats is often asymptomatic or insidious. It is unclear what factors contribute to the host's resistance. Cell-mediated immunity typically is associated with protection against facultative intracellular pathogens such as mycobacteria and seems to be associated with enhanced capacity of activated macrophages to kill mycobacteria or to inhibit their intracellular multiplication. When clinical signs occur, they reflect the site of granuloma formation. Skin lesions (found on the face, neck, forepaws and, less frequently, ventral thorax and tail base) include dermal nodules or nonhealing wounds with draining sinus tracts, often accompanied by enlarged regional lymph nodes. In pulmonary disease that occurs mainly in *M. tuberculosis* infection, bronchopneumonia, pulmonary nodule formation, and hilar lymphadenopathy are seen, causing fever, weight loss, anorexia, and harsh, nonproductive coughing. Intestinal localization, more common in *M. bovis* infection, can cause weight loss, anemia, vomiting, and diarrhea as signs of intestinal malabsorption. Mesenteric lymph nodes may be palpably enlarged, and abdominal effusion is present in some cases. Oropharyngeal lesions can cause dysphagia, retching, hypersalivation, and tonsillar enlargement. Tuberculous choroiditis and retinal detachments, granulomatous uveitis, and CNS signs occasionally occur. A granulomatous myelitis has been described in a dog with *M. avium* infection.[123] Lameness and fractures may be observed with bone localization.

623 624

Clinical laboratory findings in tuberculosis are frequently nonspecific, although leukocytosis and hyperglobulinemia may be present. Radiographically visible masses and tracheobronchial lymphadenopathy may be apparent in the thoracic cavity. Abdominal radiography and ultrasonography may reveal enlargement of parenchymatous organs such as liver and spleen or solitary abdominal masses. Fluid may be present in the abdominal cavity, and calcified mesenteric lymph nodes may be noted. Osteoproliferative lesions may be found in the axial or appendicular skeleton.

Opportunistic mycobacteriosis in cats most commonly occurs as skin lesions with multiple fistulous draining tracts associated with purulent drainage into the caudal abdominal, inguinal, and lumbar subcutaneous tissues. Most cats, even those with extensive cutaneous involvement, remain active and normal except for the draining tracts. Fever occasionally occurs, but anorexia, weight loss, and other features of chronic infection are usually absent. Dogs with opportunistic mycobacteriosis usually have a history of fight wounds or trauma followed by granulomatous proliferation of cutaneous tissues with serous or seropurulent drainage. Clinical laboratory findings are usually unremarkable in opportunistic mycobacteriosis, although hypercalcemia occurred in one cat with granulomatous skin masses.[124]

Feline leprosy is characterized by soft, fleshy, focal nodules in the skin and subcutis of the head and extremities. The lesions develop rapidly and are usually freely movable and painless. They may be haired or superficially ulcerated, and regional lymph nodes may be enlarged. Clinical laboratory findings are unremarkable.

165.3.3 Diagnosis

The diagnosis of classic tuberculosis can be established by demonstrating acid-fast organisms within a lesion by means of biopsy and histologic examination or by direct smears of exudates or fluids. The acid-fast staining method is ideal for aspirates of tissue and granulomas and for identifying organisms in bacterial cultures. Mycobacteria can be stained with carbolfuchsin or fluorescent dyes. Fluorochrome stains are more sensitive and

technically less difficult to examine than conventional carbolfuchsin stains. Although often present in low numbers, intracellular mycobacteria are recognized by their clubbed shape and beaded appearance. In *M. avium* infection, higher numbers usually can be seen. Granulomatous lesions consist of areas of focal necrosis surrounded by infiltrations of plasma cells and macrophages and an outer connective tissue capsule. Calcification of granulomas may occur.

Intradermal skin testing is used as an aid in the diagnosis of human mycobacterial infections and to evaluate delayed-type hypersensitivity in animals. Intradermal skin testing is generally useful in diseases in which the cellular immune response should be tested because humoral immunity does not play a role. Although useful in humans, intradermal tuberculin testing is inconsistent and unreliable in dogs, and is not useful in cats.[125,126] If dogs are tested, the highest concentration of the tuberculin solution used for testing humans is needed, and the inner surface of the ear pinna should be injected.[88]

Testing of antimycobacterial antibodies is unreliable in dogs and cats because antibodies are produced inconsistently. Antibody tests include hemagglutination and complement fixation but should be critically interpreted due to their inaccuracies.

Culture is the definitive means of diagnosing tuberculosis and of identifying the specific mycobacteria species involved. Mycobacteria of the tuberculosis complex are slow growing, often requiring 4 to 6 weeks to establish visible colonies. The different species can be identified by colony growth and biochemical characteristics. Culture and identification of the specific organism is helpful for definitive diagnosis, long-term management, and prognosis and for calculating the zoonotic risk.

PCR testing has been developed for species relevant in human medicine, and animal specimens can also be evaluated.[127] Commercial kits (e.g., AccuProbe; Gen-Probe, San Diego, California) simplify the identification. Although final identification in culture takes up to 6 weeks, PCR followed by restriction analysis and nucleic acid hybridization can shorten this time to a few days. Unfortunately, PCR does not exist for all species that are relevant in dogs and cats.

Confirmation of opportunistic mycobacteriosis is not always easy because a diligent search for organisms in impression smears from exudates or tissue biopsy is usually required. Histology is characterized by extensive granulomatous to pyogranulomatous inflammation of the dermis and associated panniculitis. Application of acid-fast stains may reveal a few organisms within extracellular lipid vacuoles surrounded by neutrophils and macrophages. Bacterial culture of deep tissue (especially the panniculus) biopsy specimens and identification of the organism are essential for definitive diagnosis, but cultures from multiple tissue samples may be necessary. Fast-growing mycobacteria grow within 3 to 5 days, whereas the slow-growing types require 4 to 6 weeks. A 16S rRNA PCR and partial sequencing has been used to identify *M. genavense* infection in a cat.[119]

Diagnosis of feline leprosy is made by finding large numbers of acid-fast mycobacteria on histologic or cytologic samples or impression smears. A diffuse, granulomatous inflammatory infiltrate composed of vacuolated macrophages is present on histologic examination, and numerous mycobacteria are noted within macrophages or extracellularly within dermal vacuoles. Culture results are routinely negative with standard mycobacterial media, and specific media are needed (e.g., 1% Ogawa egg yolk medium). Animal inoculation using guinea pigs, rabbits, mice, or hamsters has been performed historically to identify *M. lepraemurium,* but this technique is obsolete. A PCR amplifying a sequence of the 16S rRNA gene has been developed to detect *M. lepraemurium,*[122,128] but its availability is limited.

165.3.4 Treatment

The decision to treat a dog or cat with classic tuberculosis is controversial. The zoonotic risk of pets that may harbor *M. tuberculosis* or *M. bovis* must be considered. Species differentiation by culture or PCR is recommended, especially if the animal has generalized disease, respiratory tract involvement, or extensive draining cutaneous lesions. If treatment is opted, the owner must know that it is long term and difficult to maintain (especially in cats). The inherent toxicity of some drugs and the financial costs must be explained. In some cases, the drugs may at best suppress the disease and indefinite treatment may be required. Surgical excision of small cutaneous lesions may be considered but is successful in only a few cases, and systemic therapy should accompany the surgical procedure. Debulking of larger lesions risks wound dehiscence and local recurrence of infection.

Pending a definitive diagnosis, interim therapy with fluoroquinolones is recommended. If signs of regional spread or systemic involvement are present, double or triple therapy should be initiated immediately. Ideally, treatment should consist of an initial and a continuation phase. The initial phase usually requires at least three drugs and should last 2 months; the continuation phase requires two drugs and lasts at least an additional 4 months, depending on the type and extent of disease. Some animals require lifelong treatment. If triple therapy is not feasible (e.g., in difficult cats), treatment should at least involve two drugs, which should be given for a minimum of 9 months.

624 625

Traditionally, a combination of rifampin, isoniazid, and ethambutol (a common combination for humans) has been considered the most effective regimen for treatment of tuberculosis in animals. These drugs are relatively hepatotoxic for dogs and cats. The results of recent studies suggest less toxic combinations that are equally effective. The current treatment recommendation is an initial phase of 2 months involving a combination of rifampin (10 mg/kg given orally every 12 hours), enrofloxacin (5 mg/kg given orally every 24 hours), and azithromycin (10 mg/kg given orally every 12 hours), followed by a continuation phase of rifampin *plus* either enrofloxacin or azithromycin in these dosages. When resistance develops, a combination of rifampin, isoniazid, and ethambutol may be considered. If necessary, pyrazinamide or dihydrostreptomycin (if available) can be substituted for ethambutol. If *M. bovis* infection has been confirmed, however, pyrazinamide is not recommended due to the organism's natural resistance. Rifampin and isoniazid are more effective and less toxic than ethambutol and dihydrostreptomycin and consequently more appropriate choices if only two drugs are given. The prognosis depends on the extent and severity of infection but is generally guarded, especially when systemic disease is present. Uncomplicated cutaneous cases carry the best prognosis.[129]

In opportunistic mycobacteria infection, species identification should be performed and antibiotic susceptibility testing should be requested. A fluoroquinolone should be used pending diagnosis. Treatment after diagnosis should be tailored to the individual case. *M. fortuitum* and *M. smegmatis* are usually sensitive to high dosages of fluoroquinolones (ciprofloxacin, enrofloxacin, and ofloxacin), whereas *M. chelonae* is not. In contrast, *M. chelonae* is usually sensitive to clarithromycin. Double or triple therapy should be considered, as for tuberculosis, and antibiotic therapy should be continued for at least 2 months. In some cases clinical cure was achieved only after 6 to 8 months of therapy; other patients have required lifelong treatment. Surgical resection or debulking of large granulomatous masses has been more beneficial in dogs. Cats may improve with surgical resection of small lesions, but dehiscence, proliferation of the wound margins, and further progression of lesions are common sequelae. Surgical intervention should be radical and planned as for removing a locally invasive neoplasm. Antibiotic therapy is always necessary in combination with surgery. The prognosis is poor to guarded and is worse if previous attempts at surgery have failed. Dogs apparently have a better prognosis for

remission. Despite expensive, long-term therapy, an infected pet that has continual serous drainage occasionally must be euthanized.

In feline leprosy, surgical removal of lepromatous granulomas is the desired treatment. Complete surgical excision of all nodules has proved beneficial in many cats. A fluorquinolone should be used pending the diagnosis. When surgery is not feasible or when removal is incomplete, treatment with clofazimine (8 mg/kg given orally every 24 hours), rifampin (15 mg/kg given orally every 24 hours), or clarithromycin (5 mg/kg given orally every 12 hours) has proved successful.[122,129] Clofazimine appears to have minimal toxicity in cats. Dapsone may be another alternative to surgery but is considered relatively toxic in cats. In contrast to other mycobacterial infections, the prognosis is good, and spontaneous resolution without treatment may occur.[130]

165.3.5 Prevention and Public Health Considerations

Mycobacterial infections are a major public health problem. Humans are susceptible to all mycobacteria that cause classic tuberculosis in dogs and cats. Identification of cases of *M. tuberculosis* infection in humans and outbreaks of *M. bovis* infection in cattle should be followed by evaluation of pet contacts. However, diagnosis of exposure in a healthy animal is difficult, because intradermal skin tests and antibody tests are not reliable. Euthanasia of animals infected with *M. tuberculosis* or *M. bovis* is generally recommended due to the public risk. *M. avium, M. microti, M. microti*-like, and *M. simiae* are just as likely to be acquired from environmental sources by humans as by pets, therefore treatment can be considered. However, to avoid any potential concern, families with members who are immunocompromised generally should be advised not to keep mycobacteria-infected pets. Vaccines are available to protect humans against infection with *M. tuberculosis,* but their efficacy is questionable. The attempt to control tuberculosis in dogs with modified live vaccines has had moderate success in that some dogs have shown resistance to infection; however, the immunity was only partial, therefore vaccination has not been generally recommended.

Opportunistic mycobacteria are free-living saprophytes, and there is little risk of transmission of these infections from animal to animal or animal to human. However, wound disinfection and contact precautions are usually advised, especially if immunosuppressed individuals are present in the same environment. Subcutaneous inoculation of *M. chelonae* organisms into a person reportedly occurred through penetration of dog hair into the owner's Achilles tendon by means of prolonged, vigorous rubbing of the person's ankle. Human hospital–acquired infections have also occurred.

There is no zoonotic risk in feline leprosy. Because the disease is acquired from rodents, prevention of exposure to rodents likely minimizes the possibility of disease in cats.

165.4 BRUCELLOSIS

165.4.1 Etiology

Canine brucellosis is caused by *Brucella canis,* a small, gram-negative, aerobic, coccobacillary bacterium that naturally infects dogs, causing an insidious bacteremia and reproductive disturbances.[1] *B. canis* has a limited host range; only dogs and wild Canidae have been found to be susceptible in nature. A survey testing free-ranging coyotes in Yellowstone National Park in Wyoming did not find antibodies to *B. canis*.[132] Cats can be infected experimentally with *B. canis* but are relatively resistant. Rabbits and nonhuman primates (but no other animal species) can also be experimentally infected. Human cases have been reported as a result of laboratory accidents or contact with infected dogs, but people are relatively resistant to *B. canis*. Dogs also are

susceptible to infection with *Brucella abortus* and *Brucella suis,* which they can acquire naturally through ingestion of contaminated placentas and aborted fetuses from livestock.[133]

165.4.2 Pathogenesis

A relatively low prevalence of *B. canis* infections has been reported in the United States and Japan (1% to 18%), with a higher rate seen in the southern United States (approximately 8%). The prevalence is higher in Central and South America, with rates as high as 28%, as well as in Asia and North Africa. *B. canis* infections are extremely rare in northern Europe, but cases have been reported in southern and eastern European countries, (e.g., Spain and Czechoslovakia). The prevalence of infection varies according to a number of factors, including the age of the investigated population, housing condition, breed, and geographic location. Pet dogs in urban environments have a lower prevalence compared with stray dogs in economically depressed areas, which may reflect increased population density and uncontrolled breeding of dogs.

625

626

B. canis is most commonly transmitted venereally; the organism penetrates the mucous membranes and enters the lymphoreticular system. The infection rate is high during breeding or after abortion. The highest number of organisms is found in aborted material. Shedding of *B. canis* may occur for up to 6 weeks after an abortion. The milk of infected bitches contains lower concentrations of organisms and appears to be less important in the transmission of infection to surviving pups, most of which having already been infected *in utero*. Although only low numbers of organisms are seen in semen and urine, seminal fluid and urine have been incriminated as sources of infection in male dogs that harbor the organisms in the prostate and epididymides. Alternative means of transmission occur less frequently under natural circumstances. Transmission via fomites has been reported after vaginoscopy, blood transfusion, artificial insemination, and use of contaminated syringes. *B. canis* is short lived outside the dog and is easily inactivated by common disinfectants.

After invading the mucous membranes, the bacteria enter phagocytic cells (and persist intracellularly in mononuclear phagocytes) and are transported to lymphatic and genital tract tissues. A leukocyte-associated bacteremia occurs beginning l to 4 weeks after infection and can last 6 to 64 months. *B. canis* may also spread to nonreproductive tissues, such as the intervertebral disks, eyes, and kidneys. The greatest numbers of *B. canis* organisms are found in the lymph nodes, spleen, and tissues of gonadal steroid dependency. As with other intracellular pathogens, cell-mediated immunity is probably the most important defense mechanism against *B. canis*. Persistent, nonprotective antibodies are characteristic of such infections; they appear to have little influence on the level of bacteremia or the number of organisms in tissues but characteristically cause hyperglobulinemia.

Spontaneous recovery from infection may occur within l to more than 5 years after infection. Some dogs may have persistent bacteremia throughout this time, whereas others can harbor bacteria in tissues for several months after bacteremia ceases. Dogs that recover naturally have low or negative antibodies and yet are immune to reinfection, which also suggests that protective immunity is cell mediated.

165.4.3 Clinical Signs

Despite generalized systemic infection with *B. canis,* adult dogs rarely are seriously ill. Fever is uncommon, and lymph node or spleen enlargement may rarely be noted. Except in males that commonly have epididymitis, most infections are not diagnosed through intact history or a routine physical examination. Dry, lusterless coats, loss of vigor, and decreased exercise tolerance are occasionally reported by owners of working dogs. Nongravid females mostly show no signs of illness.

The primary problems in intact male dogs are epididymitis, scrotal enlargement, and scrotal dermatitis. Inflammation of the epididymides and testes in males causes sperm leakage, which provokes the immune system to produce a complex of antisperm agglutinating antibodies and delayed-type hypersensitivity reactions against sperm that are unrelated to the antibodies against *B. canis*. The immune responses produced against spermatozoa contribute to the epididymitis, infertility, and eventual spermatogenic arrest seen in most infected male dogs.[133]

Bitches in late gestation (40 to 60 days) usually abort dead puppies but show no other clinical signs. Puppies are usually partly autolyzed. Some puppies are stillborn or weak. Conception failures also occur, but infection with *B. canis* does not interfere with normal estrous cycles. A high proportion of bitches that abort may subsequently have normal litters. However, some infected bitches show intermittent reproductive failures.

Less often, *B. canis* may localize in nonreproductive tissues such as the end-arterial circulation of the intervertebral disk, causing diskospondylitis.[134] Other tissues that filter blood-borne organisms or immune complexes also may become involved, including eyes (uveitis), kidneys (glomerulonephritis), and meninges (meningoencephalitis). Dogs with diskospondylitis initially experience spinal pain and later paresis and ataxia if spinal cord compression develops. Osteomyelitis of the appendicular skeleton causes lameness of the affected limb. Meningoencephalitis has been reported after experimental and natural infections; however, neurobrucellosis in dogs, as in humans, is uncommon.[135] Chronic multifocal pyogranulomatous dermatitis that resembled lick granuloma lesions also has been reported, but a direct causal relationship was not established. Recurrent anterior uveitis with corneal edema has been detected in infected dogs, either alone or in combination with other signs.[133]

Hematologic and biochemical values are either unaltered or nonspecific in canine brucellosis. Hyperglobulinemia with concomitant hypoalbuminemia has been the most consistent finding in chronically infected dogs. Some dogs have a positive Coombs' test in the absence of hemolytic anemia. CSF analysis may reveal pleocytosis, primarily consisting of neutrophils, and an increased protein concentration with meningoencephalitis, but it is unremarkable when diskospondylitis alone is present. Urinalysis is usually normal despite the variable presence of bacteriuria unless glomerulonephritis is present. Semen abnormalities include immature sperm, deformed acrosomes, swollen midpieces, detached tails, and head-to-head agglutination of sperm, often accompanied by neutrophilic and mononuclear inflammation.

165.4.4 Diagnosis

Antibody testing is the most frequently used diagnostic method for detecting canine brucellosis. Antibody tests available to veterinarians, however, pose a particular dilemma because several tests currently in use by diagnostic laboratories have not been evaluated critically and may provide false-positive results.[136] These tests are subject to considerable interpretive error because lipopolysaccharide antigens of several bacterial species cross-react with *B. canis*. False-negative results are rare, but antibody tests are usually negative during the first 4 weeks after infection despite the presence of bacteremia by 2 weeks after infection. Antibiotic therapy may suppress bacteremia and the associated antibody response, contributing to negative antibody tests and failure to isolate the organism in infected dogs.

ELISA and IFA for antibody detection exist, but they have not been well standardized or widely evaluated. Some newer ELISAs have been developed,[137–139] but no comparison studies involving large numbers of canine sera samples are available to assess the usefulness of these tests. The 2-mercaptoethanol rapid slide

agglutination test (ME-RSAT) (D-Tec CB; Synbiotics, San Diego, California) is preferred as an in-office screening procedure because it is inexpensive, rapid, and sensitive and it detects antibodies early. There is a high correlation between a negative test and lack of infection. However, false-positive test results are possible. *B. canis* cross-reacts with other *Brucella* species and other bacterial species, such as *Pseudomonas, Bordetella bronchiseptica, Actinobacillus equilli* and, possibly, others. Some breeds (e.g., Irish wolfhounds and Old English sheepdogs) have an exceptionally high false-positive rate, for unknown reasons. The tube agglutination test (TAT) is used by some laboratories after a positive ME-RSAT result to obtain confirmation and quantitative titers. Unfortunately, it suffers from the same nonspecific results and has not been well standardized among laboratories. Nevertheless, results of the ME-RSAT correlate well with the ME-TAT, both of which should be considered as screening tests. The agar gel immuno-diffusion (AGID) test is a sensitive procedure for antibody detection. Two antigens, either from the cell wall or cytoplasm (Cp), have been used in this test. The better CpAg-AGID uses cytoplasmic antigens and is highly specific for *Brucella* infection in dogs.[140] This test is performed by certain commercial laboratories and should be used as a confirmatory antibody testing procedure.

626

627

Culture, if positive, is the only definitive way to diagnose brucellosis. Isolation of *B. canis* is time-consuming but not difficult, because the organism grows well aerobically on conventional media used for all *Brucella* species. Negative results, however, may occur in chronically infected dogs with intermittent bacteremia. Blood is the best source for isolating the organism. Whole blood should be cultured, because the organisms are associated with the leukocyte fraction. Bacteremia is detected 2 to 4 weeks after oronasal infection and, if left untreated, can persist for as long as 5 years.[133] Culture of the organism from urine or semen is less reliable. However, urine culture can be positive in some dogs, especially males, when blood cultures are negative; only cystocentesis urine should be used to avoid overgrowth of other bacteria. Collection of semen by ejaculation is valuable for culture during the first 3 months of infection, when the concentration of organisms is greatest. *B. canis* can also be isolated at necropsy from several tissues.

A PCR has been developed for humans that identifies all *Brucella* species relevant for human medicine; the test uses genus-specific primers that bind to a conserved region of the 16S rRNA gene. With carbohydrate profiling, *B. canis* can be differentiated from the other species.[141,142] This PCR could be used in dogs.

165.4.5 Treatment

Treatment of *B. canis* infection is difficult because of the intracellular persistence of the organism. Relapses are common after antimicrobial therapy stops. Bacteremia often recurs days to months after treatment is discontinued, making follow-up evaluation essential because animals still can harbor infection in certain tissues. For these reasons and because of the zoonotic risk, client education is critical, and euthanasia may be considered. If treatment is an option, infected pets should be neutered and given a strict regimen of antibiotic therapy to reduce the chance of family members becoming infected through genital secretions. The organism can persist in the tissues of neutered animals, but shedding is believed less likely. Treatment of intact breeding dogs should be considered only under exceptional circumstances. Infected male dogs rarely, if ever, recover; they usually become sterile. Infected female dogs have recovered in some instances and have been returned to breeding programs. Aborting females may subsequently produce normal litters, but even in those cases the success of therapy is uncertain. Thus breeding of such animals should be done only when it is considered essential (e.g., loss of a valuable blood line) and after the risk has been explained to the owner.

Various antimicrobial agents have been considered for treatment. Repeated courses of antibiotic therapy are recommended on the basis of follow-up antibody testing and blood cultures. Cure of brucellosis must not be assumed, because bacteremia may recur weeks or months after antibiotics are discontinued, and reports of

successful cures should be viewed with caution unless subsequent cultures and antibody tests have been performed for at least 6 months. Infected dogs respond poorly or not at all to drugs when they are given alone or for a single course of therapy. *In vitro,* synergy has been noted among tetracyclines and fluoroquinolones and aminoglycosides and sulfonamides,[143] and combination therapy, usually performed with tetracyclines and aminoglycosides, offers the best chance of eliminating infection. Unfortunately, the best known regimen (minocycline *plus* dihydrostreptomycin) is unobtainable in many countries because of the restricted availability of dihydrostreptomycin. Gentamicin has been substituted for dihydrostreptomycin, but the efficacy is less than with dihydrostreptomycin.[133] The recommended treatment regimen is gentamicin (5 mg/kg subcutaneously every 24 hours for 7 days) administered twice in the first and fourth week, in combination with high-dose oral minocycline (25 mg/kg orally every 24 hours) for 4 weeks. Eventually, generic doxycycline can be substituted for minocycline at the same dosage at lower cost. Renal function must be closely monitored during gentamicin treatment phases. Lower dosages of this combination or other antibiotics alone or in combination are not as effective. Infected animals may have to be treated with two or more courses of this antimicrobial treatment regimen. Sequential antibody tests at 3-to 6-month intervals are recommended to monitor treatment efficacy.

165.4.6 Prevention

There is no vaccine for brucellosis, and the results of experimental vaccination studies have been unsatisfactory. The desirability of a vaccine is questionable, especially with the available diagnostic testing, because an effective vaccine would be required to provide serviceable immunity but not confound the antibody tests.

Control of canine brucellosis in a kennel with confirmed cases is a difficult, time-consuming, and agonizing experience both for dog owners and veterinarians. A kennel should be quarantined as soon as the diagnosis of *B. canis* infection is ascertained, and infected animals should be promptly eliminated. Appropriate disinfection procedures should be implemented to arrest the spread of infection via fomites. All dogs and discharges or secretions in an infected kennel should be handled with gloves until antibody testing can be done to determine the extent of the infection. Animals should not be admitted to or released from the kennel until the disease is eradicated. Movement of dogs within a colony also should be restricted to removal of proven and suspect cases to isolation quarters. New additions are at high risk for infection, especially if dogs are not individually penned, which also increases the number of animals requiring repeated testing during the eradication process. Animals must not be released for sale or any other purpose. All dogs in an infected kennel should be antibody tested for at least 3 months after a negative status is achieved, especially before each breeding, even by artificial insemination. If animals are retained as pets or working dogs or if treatment is contemplated, the animals should be neutered and moved to separate housing. Prevention is accomplished by quarantine of all new acquisitions until two antibody test results at l-month intervals are negative. Animals used for breeding should be tested 3 to 4 weeks before each mating to allow time for test results to be reported. Brood bitches should not be mated unless both male and female have been tested and certified negative. If dogs leave a colony, they should be tested before readmission.[133]

165.4.7 Brucellosis in Cats

Cats can be infected experimentally and develop bacteremia but are relatively resistant and do not develop clinical signs. The relevance of *B. canis* infection in cats in the field is unknown.

165.4.8 Public Health Considerations

Pathogenic *Brucella* species in humans include *B. melitensis, B. abortus, B. suis,* and *B. canis*. Human brucellosis caused by other *Brucella* species is still prevalent in many southern countries, especially in the Mediterranean basin, and ingestion of raw milk and milk products is the most common mode of transmission.[142,144–146] Humans are relatively resistant to infection with *B. canis,* and the disease is relatively mild compared with infections caused by other *Brucella* species. However, more than 40 cases of human infection caused by *B. canis* exist in the literature. Natural and laboratory-acquired infections have been reported in several countries; however, the actual number of cases is unknown because human infections are often undiagnosed. Contact with aborting bitches was the source of infection for the majority of infected pet owners. A proportion of cases are asymptomatic and can be detected only by testing for antibodies. Fever, chills, fatigue, malaise, lymphadenomegaly, and weight loss have been seen in symptomatic patients. Rare complications include endocarditis,[147] meningitis, arthritis, hepatitis, and visceral abscesses. Two infected adolescent boys had pleural effusion and pulmonary nodules.[148] Human infections are readily and effectively treated with tetracyclines.

627 628

Clients should always be informed about the potential health hazard in keeping *B. canis*–infected pets. Laboratory workers should use caution in handling or pipetting samples submitted for diagnostic testing. Veterinarians should practice good hygiene when examining suspected dogs, especially aborting bitches.

165.5 TETANUS

165.5.1 Etiology

Tetanus is caused by the action of a potent neurotoxin formed in the animal or human body by *Clostridium tetani,* a motile, gram-positive, nonencapsulated, anaerobic, spore-forming bacterium.[1] Although strain differences of *C. tetani* exist throughout the world, the toxin produced by all strains is antigenically homogeneous. Resistant spores of the organism can be found in the environment, especially in rich soil. Spores can survive adverse weather conditions in the absence of direct sunlight for months to years and can be found readily in dust and debris in indoor environments. Organisms can be isolated from the feces of many domestic animals, including dogs and cats, and humans without pathogenetic significance.[149] The prevalence of the disease in dogs and cats is relatively low[150] compared with that in other domestic animals (e.g., horses) and humans. However, a number of cases in dogs[151–160] and cats[161–167] are reported in the literature. The low prevalence in dogs and cats is mainly related to the natural resistance of dogs and cats to the toxin. It could be shown that this resistance is caused by the inability of the toxin to penetrate and bind to nervous tissue, because direct CNS injection of toxin produce equivalent signs in all species.[168]

165.5.2 Pathogenesis

Tetanus develops when spores are introduced into wounds or penetrating injuries. Most cases develop after penetrating skin wounds, but tetanus has also been described in female dogs after parturition[169] or ovariohysterectomy.[170,171] The spores vegetate in response to anaerobic conditions at the site of the injury. Two toxins have been identified from *C. tetani*. Tetanolepsin causes hemolysis of erythrocytes *in vitro* but is not considered clinically significant. In contrast, tetanospasmin enters the body from the wound site and has

marked effects on neurologic function. It is not absorbed from the gastrointestinal tract, where it is usually destroyed by digestive enzymes. Its high molecular weight (176,000) precludes its entry into the placenta.

Tetanospasmin enters the axons of the nearest motor nerves at the neuromuscular endplate and migrates by retrograde transport within motor axons to the neuronal cell body in the spinal cord or brain stem. It can spread in the CNS in this fashion. Alternatively, it can be transported in the bloodstream from the area of the wound to nerves at distant sites. Thus the condition can cause localized, progressive illness or a more generalized syndrome. Tetanospasmin blocks inhibitory transmission to motor neurons. It has additional effects on the neuromuscular junction and autonomic ganglia that can cause further visceral and motor neuron disturbances.

165.5.3 Clinical Signs

Clinical signs of tetanus usually occur within 5 to 10 days of injury, but because of the higher resistance of dogs and cats, the onset may be delayed up to 3 weeks. This may account for the absence of a detectable wound by the time dogs show clinical signs. Because cats have an even more pronounced innate resistance, their wounds are usually so extensive that they are still obvious at presentation. Wounds nearer the head are associated with more rapid onset and generalized tetanus than are injuries to distant extremities.

The clinical signs of tetanus can be explained by the pathophysiologic effects of tetanospasmin on the nervous system. The toxin inhibits release of glycine and gamma-aminobutyric acid (GABA) neurotransmitters of inhibitory neurons of the brain and spinal cord. It has an affinity for gangliosides in the gray matter of the CNS, which may explain the cerebral signs that appear in some cases without obvious spinal cord involvement. Tetanospasmin also has an affinity for binding at the neuromuscular junction, which can induce direct neuromuscular facilitation before the migration of toxin to the CNS. The toxin may affect sympathetic preganglionic neurons in a manner similar to that in the lower motor neurons in the spinal cord and cause signs of autonomic dysfunction.[168]

Localized tetanus is more common in cats than in dogs and more common in dogs than in other domestic animals or humans because of the relative resistance of carnivores to the toxin. This condition is characterized by increased stiffness of a muscle or an entire limb, first noted in close proximity to the wound site. The stiffness usually spreads gradually and eventually may involve the entire nervous system.

Animals affected with generalized tetanus generally have a stiff gait and an outstretched or dorsally curved tail. They have difficulty standing or lying down in comfortable positions because of their extreme muscle rigidity. The rectal temperature is usually elevated due to excessive muscular activity. The ears are held erect, the lips are drawn back, and the forehead is often wrinkled as a result of facial muscle spasm. The animal characteristically appears to be continuously smiling *(risus sardonicus)*. Protrusion of the third eyelid and enophthalmus result from retraction of the globe from hypertonus of extraocular muscles. Trismus (lockjaw) is caused by contraction of masticatory muscles. Increases in salivation and the respiratory rate, as well as laryngeal spasm and dysphagia, can result from involvement of parasympathetic and somatic cranial nerve nuclei. Regurgitation and gastroesophageal reflux may result from esophageal hiatal hernia and megaesophagus,[172] potentially leading to aspiration pneumonia, a major complication in many animals with tetanus. Animals become apprehensive and react strongly to tactile or auditory stimulation. Dogs and cats usually remain conscious until they develop convulsions. The signs may proceed to periodic generalized tonic contraction of all muscles with opisthotonus or grand mal convulsions.

Bradycardia associated with tetanus probably results from vagal-parasympathetic hyperactivity. Tetanospasmin also blocks neurotransmitters in the parasympathetic cardiac inhibitory center of the nucleus ambiguous,

resulting in increased vagal tone and pronounced bradyarrhythmias. Increased catecholamine release associated with adrenergic stimulation can cause episodes of hypertension or tachycardia.[173]

Hematologic abnormalities, including leukocytosis with neutrophilia and left shift, are the result of large wounds or aspiration pneumonia that may be present. Serum biochemistry and CSF values are unaffected, except for increased muscle enzyme activities (creatine kinase, aspartate aminotransferase). 628 629

The progression of clinical signs culminates in death, which is usually caused by respiratory compromise as a result of rigidity of the respiratory musculature, reflex spasms of the larynx, increased airway secretions, and central respiratory arrest from medullary tetanospasmin effects or anoxia. Dogs and cats not as severely affected may recover. The binding of tetanospasmin to presynaptic sites of inhibitory neurons is irreversible; recovery depends on sprouting of new axon terminals.

165.5.4 Diagnosis

Tetanus is one of the few infectious diseases that can be diagnosed by "classic" clinical signs. Measurement of serum antibody titers to tetanospasmin has been used to substantiate the diagnosis. Values must be compared with those of control animals. Antibody measurements might be helpful in a clinical setting to confirm the cause of undiagnosed muscle stiffness. Isolation of *C. tetani* from wounds is usually unrewarding. The organisms are only present in low concentrations, and although Gram-stained smears may demonstrate gram-positive rods and dark-staining spherical endospores, the morphology is similar to that of many other anaerobic bacteria. If culture is attempted, it should be done under strict anaerobic conditions at 37° C for at least 2 weeks.

165.5.5 Treatment

Treatment of severely affected animals is costly and time-consuming, and owners must be advised of the possibility of complications and lengthy hospitalization. Mildly diseased animals recover from the neurologic dysfunction with wound management alone. More severe cases, if left untreated, can prove fatal. These animals are suffering, therefore euthanasia must be the alternative to treatment.

The immediate concern in treating tetanus is administration of antitoxin to neutralize any toxin that is unbound to the CNS or has yet to be formed. The timing and route of antitoxin administration are important in determining effectiveness. Use of antitoxin should be a routine measure; however, elimination of bound toxin by the affected animal occurs gradually, and administration of antitoxin does little to hasten the process. Therefore recovery in most cases is slow and progressive. Intravenous administration of antitoxin is superior to intramuscular or subcutaneous administration for producing a rapid and marked increase of circulating antitoxin. The equine antitoxin (2.5 to 25 IU/kg) should be given slowly intravenously over 5 to 10 minutes. Larger animals should receive a proportionally lower dose on the basis of body weight. Intravenous administration of antitoxin is commonly associated with anaphylaxis, warranting appropriate precautions. An initial test dose (0.1 to 0.2 mL) of antitoxin should be given intradermally 15 minutes before IV administration. Epinephrine, glucocorticoids, and antihistamines should be readily available in case of an adverse reaction, or the latter two may be given before the intravenous injection, depending on the intradermal test outcome. A therapeutic blood level of antitoxin persists in dogs for 14 days after injection; repeated administration is usually unnecessary and increases the chance of an anaphylactic reaction. Local intramuscular injection of a small dose of antitoxin (1000 IU) around and proximal to the wound site has been shown to be beneficial in experimental studies. Intrathecal injection of antitoxin in laboratory animals has been shown to be beneficial; however, use in affected humans has not proven to be effective.

Local and parenteral antibiotic therapy should be instituted in an attempt to kill any vegetative *C. tetani* organisms present in the wound. Although antibiotics by themselves do not neutralize circulating toxin, they significantly reduce the amount of antitoxin released in experimental tetanus. Penicillin G is the drug of choice and should be given intravenously (as potassium or sodium salt) at a high dose (20,000 to 50,000 IU/kg every 6 hours for 10 days). A portion of the dose can be injected intramuscularly (as procaine salt) in close proximity to an identified wound site. Penicillin derivatives, such as ampicillin, are not as effective against the organism, and their use may cause little or no response. Metronidazole (10 mg/kg orally every 8 hours for 10 days) may be more active than penicillin G because it is bactericidal against most anaerobes and achieves effective therapeutic concentrations even in anaerobic tissues. Some treatment regimens recommend a combination of penicillin G and metronidazole; however, metronidazole toxicity has to be considered, and only low dosages should be used (not more than 250 mg total every 12 hours in cats). Clindamycin (5 mg/kg intravenously every 8 hours for 10 days) also has been used in some cases.

Surgery may be required if tissue necrosis or abscess formation is extensive. Antitoxin should be administered before surgery because of the release of toxin in the circulation during tissue manipulation. General anesthesia is usually required to debride wounds and remove necrotic tissue. The prognosis for recovery is always greater if the wound site is located and can be debrided.

Supportive measures are imperative in the successful management of an animal with tetanus. Sedation is usually needed for an excitable animal, and phenothiazines appear to be highly effective, even though they are contraindicated in most seizure disorders. Fluids are needed for hydration. Tracheostomy may be required if laryngeal spasm is severe. Esophagostomy or gastrostomy tubes may be needed if trismus prevents eating.

In mildly affected animals, normal function usually returns within 3 weeks of the initiation of treatment. The prognosis for severely affected animals is extremely guarded, and many die as a result of complications associated with respiratory or cardiovascular dysfunction or uncontrollable muscle spasms.

165.5.6 Prevention

Active immunoprophylaxis with tetanus toxoid is not recommended for dogs and cats; it is used in more susceptible species such as humans and horses. Appropriate care of infected wounds and rational antibiotic therapy should minimize the occurrence of tetanus.

165.5.7 Tetanus in Cats

Cats are even more resistant to tetanus toxin than dogs and more commonly develop only localized tetanus.[161–167]

165.5.8 Public Health Considerations

There is no risk of transmission from dogs or cats to humans.

165.6 BOTULISM

165.6.1 Etiology

Clostridium botulinum is a gram-positive, spore-forming, saprophytic, anaerobic rod that is distributed in soil worldwide. Botulism is an intoxication caused by a neurotoxin produced by the organism that causes neuromuscular paralysis.[1] In humans, outbreaks of botulism are commonly described in the literature; the contaminated food sources are variable and have included canned beef stew,[174] home-canned mushrooms,[175] and restaurant potato salad.[176] Sources of recent outbreaks include a commercial canned cheese sauce in the United States,[177] a mascarpone cream cheese dessert in Italy,[178] and a locally produced cheese in Iran.[179]

629

630

To cause disease, either the organism or its spores must contaminate a food source. Most cases in animals are caused by ingestion of the preformed toxin in food. Naturally occurring botulism in dogs has been mainly attributed to the eating of carrion or raw meat. The disease in cats is similar to that in dogs under experimental conditions, although there are no reports of naturally occurring disease.

Seven subtypes of *C. botulinum* (A, B, C, D, E, F, and G) have been identified on the basis of their antigenically distinct neurotoxins. All have similar structure and the same neurotoxic effect. Subtypes A, B, E, and F are associated with human disease. Most cases in animals are caused by subtypes C and D, which are closely related immunologically. All canine cases to date have been caused by subtype C toxin[180–186] with the exception of two cases of subtype D reported from Senegal.[187,188]

Clostridial spores are resistant to heat, light, drying, and radiation, and specific conditions are necessary for germination. The organism grows best in anaerobic and warm conditions (15° to 45° C). All types of botulinal toxin are inactive when initially released by bacterial lysis, and bacterial or tissue proteases are necessary to cleave them to generate the active dichain neurotoxin.

165.6.2 Pathogenesis

Botulism is usually caused by ingestion of the preformed toxin, although a variant of the disease in humans, infant botulism, is induced by ingestion of spores, mostly present in honey. Adults are usually resistant to intestinal coloniza-tion with *C. botulinum,* mainly thanks to the intestinal microflora.

Once ingested, the toxin is absorbed from the stomach and upper small bowel and enters the lymphatic system. It circulates by unknown transport mechanisms to the neuromuscular junction of cholinergic nerves, where it exerts its effects. A metalloproteinase similar to tetanus toxin, the botulinal toxin, prevents the presynaptic release of acetylcholine at the neuromuscular junction; both the spontaneous release of acetylcholine and its release caused by a nerve action potential are inhibited. Binding of the toxin occurs very quickly and is irreversible, unaffected by temperature and independent of neural activity. The cell membrane receptors for the toxin have a very high affinity for it because very small quantities (less than 10 mol) are sufficient to cause death, making it the most potent toxin known.[189] Variations in receptor affinity for different types of toxin explain the different sensitivities of animal species to the different botulinal toxins.

165.6.3 Clinical Signs

The incubation period after ingestion of contaminated food in dogs ranges from hours to 6 days. The earlier the signs appear, the more serious the disease. The duration of illness in dogs that have recovered ranged from 14 to 24 days. The severity of signs varies with the amount of toxin ingested and the individual susceptibility.

The blockage of acetylcholine release results in generalized lower motor neuron and parasympathetic dysfunction. Clinical signs are characterized by a symmetric, ascending weakness from the rear to the forelimbs that can result in quadriplegia. Limb reflexes are depressed, and cranial nerve motor responses are affected, causing mydriasis, decreased jaw tone, decreased gag reflexes, and excess salivation. Megaesophagus may be present. Pain perception is intact; muscle atrophy and hyperesthesia do not develop. Death may result from respiratory paralysis.

Hematologic and biochemical parameters are unaffected. Electromyography shows conduction defects primarily in the neuromuscular junction and less in the peripheral nerve.

Blockage of neurotransmission can cause death of the affected animal from inability to breathe. If recovery occurs, it is complete. Botulinal neurotoxin does not cause death of the affected neuron; it only causes paralysis and degeneration of the intoxicated synapse. If the animal survives, recovery occurs by development of new terminal axons with functional neuromuscular junctions. Cranial nerve, neck, and forelimb functions tend to return first during recovery. Thus the effect of botulinal neurotoxin always has the potential for a complete reversal.

165.6.4 Diagnosis

Botulism is usually suspected from the history and clinical signs. Confirmatory diagnosis is based on finding the toxin in serum, feces, vomitus, or samples of the food ingested. Serum should be collected as early in the disease course as possible and when clinical signs are maximal. About 10 mL of serum or 50 g of feces, vomitus, or food are needed. The preferred method for identifying the toxin still is the neutralization test in mice. Serum or an extract of contaminated material is injected alone and in combination with type-specific antitoxin into the peritoneal cavity of mice. The mice are then observed for signs of botulism. Survival of one group protected with one type of antitoxin and death of the other groups with signs consistent with botulism confirm the presence of botulinal toxin. Newer *in vitro* tests, including radioimmune assay (RIA), passive hemagglutination, ELISA,[190] and PCR, have been developed to identify botulinal toxin but have not replaced the mouse test to date due to lack of accuracy.

165.6.5 Treatment

Antitoxin is not effective after the toxin has penetrated the nerve endings, which occurs rapidly after the toxin enters the bloodstream. However, antitoxin may prevent further toxin binding if intestinal absorption and circulation are still occurring. Most cases in dogs are type C; thus type C antitoxin should be given. The recommended dose for treating dogs is the same as that for treating human adults (10,000 to 150,000 IU/dog IV or IM, two doses 4 hours apart). Because the antitoxin remains in circulation for 40 days after administration, there is no need for further administration. Anaphylaxis is a potential risk. Intradermal skin testing can be performed with 0.1 mL 20 minutes before intravenous injection. Any immediate reaction at the test site is a warning that an allergic response may occur, and glucocorticoids and antihistamines should be applied *before* application of the antitoxin in these cases.

The use of antibiotics in botulism is the subject of debate. Penicillin and metronidazole have been administered in dogs and humans in an attempt to reduce any potential intestinal growth of *C. botulinum*. The efficacy of these drugs is doubted because the disease occurs usually due to ingestion of preformed toxin and because neither drug is certain to eradicate *C. botulinum* from the intestine. The possibility that these drugs could make the disease worse by releasing more toxin through bacterial lysis is discussed. Even in infant botulism, which may involve intestinal colonization with *C. botulinum,* penicillin has no effect on recovery. Antibiotics also can alter the intestinal microflora, which might allow *C. botulinum* to grow. Therefore antibiotics should only be given if secondary infection (e.g., aspiration pneumonia) develops. Aminoglycosides should be avoided because they also have the potential to block neuromuscular function.

Supportive treatment, which can be time-consuming and expensive, is the most important intervention in the therapy of animals with botulism. Spontaneous and complete recovery occurs in moderately affected animals if respiratory and urinary tract infections can be avoided. Affected animals should be padded when recumbent and assisted to eat and drink. Several drugs, including guanidine hydrochloride, 4-aminopyridine, and 3,4-diaminopyridine, have been used as neuromuscular potentiators but without demonstrable efficiency in clinical cases in humans or animals.

631

165.6.6 Prevention

Preventing access to carrion and thorough cooking of any food fed to dogs and cats prevents the disease. Botulinal toxin is destroyed by heating food to 80° C for 30 minutes or to 100° C for 10 minutes. Vaccination with a toxoid has been successful in cattle and in exposed laboratory workers but has not been used in dogs or cats is not recommended because of the low prevalence of the disease.

165.6.7 Botulism in Cats

Although botulism has been experimentally produced in cats, no natural cases of botulism have been reported. A cat that ate contaminated yogurt did not become ill, even though two humans eating the same yogurt did. Botulism has been reported in lions, but jaguars and coatis eating the same food as the lions were not affected.[191] Produced under experimental conditions, the disease in cats is similar to that occurring in dogs because botulinal neurotoxins cause similar signs in all species. Although there are no reports of natural disease in cats, cats can be the source of outbreaks in cattle. In one case, 427 Holstein cattle that had been fed a rotten bale of oat hay contaminated with a dead cat died from botulism, and the presence of botulinum toxin type C was identified.[192]

165.6.8 Public Health Considerations

The disease is not transmitted from animals to humans.

166 CHAPTER • 166 Obligate Intracellular Bacterial Pathogens

Edward B. Breitschwerdt

166.1 GENERAL CONSIDERATIONS

From an evolutionary and clinical perspective, several groups of bacteria have developed an obligate intracellular life style that facilitates their existence within an insect vector or within one or more animal hosts. Due to the persistent nature of many of these intracellular infections, the factors that ultimately predispose to the development of pathology in many animal hosts are as yet incompletely understood. Recent genetic analyses of 16S rRNA genes, heat shock, and surface protein genes have resulted in a substantial reclassification of the genera *Anaplasma*, *Ehrlichia*, *Cowdria*, *Neorickettsia*, and *Wolbachia*.[1] As a result, the genus *Ehrlichia* is now comprised of: *E. canis*, *E. chaffeensis*, *E. ewingii*, *E. muris*, and *E. ruminantium*. The genus *Anaplasma* is now comprised of: *A. phagocytophilum*, (previously *E. equi*, *E. phagocytophila*, or the human granulocytic ehrlichia [i.e., the HGE agent]), *A. bovis*, and *A. platys. E. risticii* has been transferred to the genus *Neorickettsia,* which includes: *N. sennetsu*, *N. helminthoeca, N. risticii*, and the salmon fever agent. Organisms within the genus *Wolbachia* are currently recognized as arthropod pathogens or symbiotes but appear to be of emerging importance as vertebrate pathogens. Within the genera *Rickettsia*, *Ehrlichia*, *Anaplasma*, and *Neorickettsia*, numerous species can be pathogenic for animals, including man. Many of these organisms are found throughout the world and can be transmitted by ticks, fleas, chiggers, or the ingestion of insects or flukes. These organisms can induce disease manifestations that range in severity from subclinical to life threatening.

Because of this reclassification, clinicians will have to reorganize the nomenclature that involves pathophysiology, diagnosis, treatment, and preventive strategies related to these organisms.[1,2] Although a currently cumbersome task, the recent reclassification should result in enhanced clarity when considering similarities and differences among organisms in the same or different genera. The terms *rickettsioses*, *ehrlichioses*, *anaplasmoses*, and *neorickettsial infections* have taken on new clinical meaning as a result of advances in microbial genetics and clinical medicine. A more detailed description of Rocky Mountain spotted fever (RMSF), typhus group rickettsiae, canine ehrlichiosis, salmon-poisoning disease, and *Coxiella burnetii* infection is provided in the fifth edition of this text (see Chapter 86, The Rickettsioses).

166.2 RICKETTSIOSES: THE SPOTTED FEVER GROUP RICKETTSIAE

Spotted fever group (SFG) rickettsiae have been described from all continents. The group includes nine species: *Rickettsia rickettsii* (the type species), *R. africae*, *R. akari, R. australis*, *R. conorii*, *R. montana*, *R. parkeri*, *R. rhipicephali*, *R. sibirica*, and *R. felis*, although many other SFG rickettsiae have been described. *Dermacentor, Rhipicephalus, Haemaphysalis,* and *Amblyomma* species ticks transmit SFG rickettsiae. Rickettsia-induced endothelial cell damage results in vasculitis, altered vascular permeability, edema, and necrosis. *R. felis*, which is transmitted by fleas, is recognized as a cause of human febrile illness in the United States and Central and South America. The pathogenicity of *R. felis* in cats or dogs has not been established. As the most pathogenic of the SFG rickettsiae, *R. rickettsii* will be considered in detail.

166.3 ROCKY MOUNTAIN SPOTTED FEVER

RMSF is a tick-transmitted rickettsial disease of dogs, people, and other vertebrate species. The causative agent is *Rickettsia rickettsii*. Veterinarians should anticipate a spectrum of illness after naturally occurring infection with

R. rickettsii in endemic regions. Clinical abnormalities associated with RMSF include fever, anorexia, depression, mucopurulent ocular discharge, scleral injection, tachypnea, coughing, vomiting, diarrhea, muscle pain, neutrophilic polyarthritis, and a diverse group of neurologic signs including hyperesthesia, ataxia, vestibular signs, stupor, seizures, and coma. In some dogs, weight loss is very severe, considering the short duration of illness. Poorly localizing joint, muscle, or neurologic pain that is suggestive of polyarthritis, polymyositis, or meningitis may represent the only or most prominent clinical finding. Retinal hemorrhages are a consistent finding but may be absent early in the course of the disease. Epistaxis, melena, hematuria, and petechial-to-ecchymotic hemorrhages occur in some dogs but may not develop unless diagnosis and treatment are delayed for 5 or more days after the onset of clinical signs. Scrotal edema, hyperemia, hemorrhage, and epididymal pain are frequently observed in male dogs. Signs associated with cardiovascular collapse, oliguric renal failure, or brain death can develop in the terminal stages of the disease.[3,4] Gangrene affecting the distal extremities, scrotum, mammary glands, nose, or lips is associated with severe vascular obstruction and can induce substantial tissue loss, necessitating reconstructive surgery.

166.3.1 Diagnosis

Seasonal occurrence, history of tick infestation, fever, and combinations of the previously described clinical findings should suggest the possibility of RMSF. Due to marked variation in clinical presentation, confirmation of the diagnosis of RMSF is important for the clinician to gain familiarity with the disease. In addition, confirmation of RMSF in household pets warrants owner education as to the enhanced risk associated with tick exposure in that environment. Thrombocytopenia, generally mild in degree, is the most consistent hematologic finding.

Leukopenia generally occurs during the early stages of infection (first 24 to 48 hours), followed by progressive leukocytosis, which increases in proportion to the severity of vascular injury. Toxic granulation of neutrophils, metamyelocytes, eosinopenia, lymphopenia, and monocytosis may accompany the more typical changes in platelet and neutrophil number. A mild anemia may occur. Severe anemia, leukopenia, and thrombocytopenia can accompany fulminant canine RMSF.[4] Biochemical abnormalities reflect the effects of generalized vascular damage and vary with the severity and duration of infection. Hypoproteinemia, hypoalbuminemia, azotemia, hyponatremia, hypocalcemia, and increased liver enzymes (serum alkaline phosphatase, alanine aminotransferase) may occur in dogs with RMSF. Bilirubinuria and bilirubinemia also occur in dogs with RMSF. Synovial or cerebrospinal fluid (CSF) analysis will generally reflect a mild increase in protein and cells, which, in the early disease process, are composed of a high percentage of neutrophils and later, mononuclear cells.

Confirmation of a diagnosis requires either direct immunofluorescent testing for *R. rickettsii* antigen in tissue biopsy or necropsy specimens, serologic testing, or polymerase chain reaction (PCR) amplification of rickettsial DNA. Using the indirect fluorescent antibody (IFA) test, documentation of a fourfold or greater increase in antibody titer between acute and convalescent sera confirms a diagnosis of RMSF. To facilitate the accurate interpretation of serologic results, it is important to obtain the acute-phase sample as early in the disease course as possible and the convalescent sample 2 to 3 weeks thereafter. If acute-phase sera are obtained several days after the onset of clinical signs, a high antibody titer may be found. Although early initiation of antirickettsial antibiotic therapy will slightly decrease the intensity of the humoral immune response to *R. rickettsii* antigen, experimental studies indicate that collection of appropriately timed serum samples should still facilitate an accurate diagnosis of RMSF in dogs.[5] Direct immunofluorescent testing or PCR amplification of *Rickettsia* DNA provides the opportunity for rapid diagnosis by demonstrating *R. rickettsii* in skin biopsies or by detecting

DNA in blood or tissue samples.[6] Prior initiation of antibiotic therapy can cause a false-negative test results with both direct immunofluorescent testing and PCR.

166.3.2 Treatment

Tetracycline (22 mg/kg three times a day for 14 days) or doxycycline (5 mg/kg twice a day for 14 days) is effective for treatment of SFG rickettsiae infection. Fluoroquinolones, such as enrofloxacin, appear to be equally effective for treating RMSF but not ehrlichiosis. After initiation of treatment, a rapid clinical response occurs in dogs without severe vascular damage or neurologic sequela. Defervescence should be anticipated within 24 hours after the initiation of antibiotics. Delay in diagnosis or the use of antibiotics such as penicillin, cephalosporin derivatives, or aminoglycosides that lack anti-rickettsial spectrums, may result in increased morbidity or mortality. Due to severe vascular damage, fluid therapy should be used with extreme caution. Prednisolone administered at anti-inflammatory or immunosuppressive doses in conjunction with doxycycline does not potentiate the severity of *R. rickettsii* infection in experimentally infected dogs.[5]

166.3.3 Prevention

Immunity after natural infection is probably permanent. It is possible that undiagnosed mild or asymptomatic *R. rickettsii* infections, or repeated exposure to nonpathogenic SFG rickettsiae, can also contribute to the prevention of severe RMSF in dogs with heavy tick exposure in endemic regions. Minimizing tick exposure, using acaracidal preparations, and routinely removing ticks from dogs represent the most effective means of prevention. After infection with *R. rickettsii*, the duration of rickettsemia is brief, approximately 5 to 14 days.[5,6] Therefore infected dogs do not play an important reservoir role and pose a minimal zoonotic threat to humans. In contrast, if RMSF is diagnosed in a household pet, the dog serves as a valuable environmental sentinel for potential human exposure to infected ticks. Care should be exercised in removing ticks, so as not to contaminate one's hands with infective hemolymph from ticks. Although the risk of inadvertent transmission is small, contact with rickettsemic blood during intravenous catheter placement, blood collection procedures, or laboratory sample analysis should be avoided. Zoonotic warning labels are recommended for blood samples obtained from dogs in which a differential diagnosis of RMSF is being considered. The role of typhus group rickettsiae as canine pathogens is yet to be established.[7]

166.4 CANINE EHRLICHIOSIS

Canine ehrlichiosis is an infectious disease of dogs, caused by *E. canis*, *E. chaffeensis*, *E. ewingii*, and potentially *E. ruminantium*.[2,8] Although the clinicopathologic course of disease can vary depending upon the infecting *Ehrlichia* species, illness is typically characterized by an acute reduction in cellular blood elements, most often thrombocytopenia. Investigators from South Africa have obtained molecular evidence (16S rDNA sequencing) that supports infection of dogs and people with an organism that is identical or closely related to *E. ruminantium* (previously *Cowdria ruminantium*). The implications of this recent finding could prove to be of great importance, if *E. ruminantium*, the organism that causes heartwater in cattle in Africa, could be introduced into the United States by way of dog transport.

Historically, *Ehrlichia* species were designated by their cellular tropism (i.e., monocytes, granulocytes, platelets). 632
With the advent of species-specific molecular diagnostic testing, defining an infection in an animal based solely 633
upon the putative cell tropism is of minimal scientific or medical utility for several reasons. As an example, granulocytic morulae can be found on stained blood smears from dogs infected with *E. ewingii* or *A.*

phagocytophilum. Based upon current nomenclature, one dog has ehrlichiosis and the other anaplasmosis. In addition, detection of morulae is a highly insensitive means of diagnosis, which further limits the clinical utility of a cell tropism–based classification.

The distribution of canine ehrlichiosis is related to the distribution of the vector ticks, *Rhipicephalus sanguineous*, the brown dog tick and vector for *E. canis* throughout the world, as well as *Amblyomma americanum*, the lone star tick and primary vector for *E. chaffeensis* and *E. ewingii* in the United States. It is probable that other tick species transmit known and yet to be characterized *Ehrlichia* spp. to wild and domestic animals in Europe, Asia, Africa, and South America. Although ehrlichiosis is diagnosed most frequently in dogs living in the Southeastern and Southwestern United States, the disease has been reported from nearly every state. Because of chronic, subclinical infection,[9] a dog can be transported from an endemic to a nonendemic region and subsequently develop disease manifestations years after the initial infection.

E. canis and *E. chaffeensis* are small, pleomorphic bacteria that most frequently infect circulating mononuclear cells. *E. canis* infections have been reported in dogs that have a concurrent infection with *Anaplasma platys, Babesia canis* or *Hepatozoon canis*, *Bartonella vinsonii (berkhoffii)* or in conjunction with *E. chaffeensis* or *E. ewingii*. In some instances simultaneous transmission of organisms from vector ticks occurs, whereas in other instances coinfection reflects frequent tick exposure and multiple independently obtained chronic infections. Concurrent infection with phaeohyphomycosis or cryptococcosis may represent coincidental infections, or it may represent secondary opportunistic infection associated with chronic ehrlichiosis.

Clinical signs during the acute phase of disease will vary from depression, anorexia, and fever to severe loss of stamina, weight loss, ocular and nasal discharges, dyspnea, lymphadenopathy, and edema of the limbs or scrotum. Acute-phase clinical signs are transient and usually resolve in 1 to 2 weeks without treatment. Thrombocytopenia and leukopenia generally occur 10 to 20 days after infection. Despite moderate to severe thrombocytopenia, hemorrhages are rarely observed. A variety of ocular and central nervous system (CNS) signs, including hyperesthesia, muscle twitching, and cranial nerve deficits, may occur due to inflammation or bleeding into the eye or meninges respectively.[9,10] Clinical findings in the acute phase of ehrlichiosis can be identical to canine RMSF. Clinical signs associated with the chronic phase of the disease would be characterized as mild to asymptomatic in some dogs and severe in other dogs. A combination of bleeding tendencies, pallor due to anemia, severe weight loss, debilitation, abdominal tenderness, anterior uveitis, retinal hemorrhages, and neurologic signs consistent with meningoencephalitis, typify dogs that develop disease manifestations during chronic infection with *E. canis*, *E. chaffeensis,* or *E. ewingii*. Concurrent bacterial infections may be documented, particularly in neutropenic dogs. Numerous patterns of hemorrhage may occur in dogs with ehrlichiosis. Epistaxis, once considered a hallmark of the disease, is reported infrequently in more recent case series.

In addition to hematologic abnormalities that would be consistent with *E. canis* (anemia, neutropenia, thrombocytopenia, lymphocytosis, monocytosis, and eosinophilia) infection with *E. ewingii* causes neurologic dysfunction and lameness involving one or more limbs, muscular stiffness, a stilted gait, reluctance to rise, an arched back posture, and joint swelling and pain.[11,12] Polyarthritis or meningoencephalitis, characterized by a predominantly neutrophilic inflammatory response and generally accompanied by fever, is frequently reported. Morulae can be found in joint or CSF and have been observed most frequently in peripheral blood neutrophils from dogs receiving glucocorticoid or cancer chemotherapeutic drugs. Although the importance of this clinical observation is unclear, it may suggest that chronically infected dogs develop ehrlichiemia if immunosuppressed or that immunosuppression potentiates morulae development during an acute infection. Asymptomatic infections with *E. ewingii* have been documented with PCR testing.[11,12]

In addition to clinical signs that may be suggestive of ehrlichiosis, severe laboratory abnormalities can contribute to the index of suspicion for the disease.[13,14] Hematologic abnormalities including pancytopenia, aplastic anemia, neutropenia, or thrombocytopenia, would be consistent with canine ehrlichiosis. Thrombocytopenia is the most consistent hematologic abnormality in both the acute and chronic stages of ehrlichiosis.[14,15] However, after experimental infection, platelet numbers are frequently in the low laboratory reference range. Pancytopenia is documented in less than 25% of dogs in retrospective clinical studies. Profound lymphocytosis, accompanied by atypical or reactive lymphocytes, has been associated with ehrlichiosis. Because *E. canis* causes defective platelet function, bleeding can be detected in dogs with normal, increased, or mildly suppressed platelet counts. Moncytic morula in peripheral blood smears or buffy coat smears is consistent with a diagnosis of *E. canis* or *E. chaffeensis,* whereas neutrophilic morulae are consistent with a diagnosis of *E. ewingii*, which has been most frequently described in dogs in Missouri, Oklahoma, Tennessee, North Carolina, and Virginia. Anemia, if present, will vary in degree of severity among affected dogs. Positive Coombs' tests suggest that immune damage, due to circulating erythrocyte antibodies, can contribute to an acute hemolytic crisis in some dogs with ehrlichiosis. In this situation, a regenerative anemia may be encountered; however, a nonregenerative anemia is most frequently documented in chronically infected dogs. Although highly variable, bone marrow examination usually reveals a hypocellular marrow with varying degrees of suppression of the erythroid, myeloid, and megakaryocytic series. Hyperplasia of the bone marrow, especially megakaryocytic hyperplasia, occurs during the acute phase of the disease. Although encountered in other chronic inflammatory diseases, plasmacytosis is a frequently reported bone marrow finding in ehrlichiosis.

Serum proteins are increased above expected values in approximately 50% to 75% of *E. canis* seropositive dogs.[13] Hyperglobulinemia is characterized by increased beta or gamma globulins (or both). Serum protein electrophoresis may reveal a polyclonal or monoclonal gammopathy. A monoclonal gammopathy, in association with severe bone marrow plasmacytosis, could be easily misdiagnosed as a plasma cell myeloma or, when found in association with lymphocytosis, misdiagnosed as lymphocytic leukemia. Hypoalbuminemia occurs in association with protein-losing nephropathy (PLN) or a reciprocal decrease in albumin associated with hyperglobulinemia. Experimentally, a transient, spontaneously reversible PLN associated with ultrastructural glomerular damage occurs 2 to 5 weeks postinoculation. In the chronic disease phase, *E. canis* can induce a severe PLN most likely related to immune complex glomerulonephritis. Less frequently encountered laboratory abnormalities include azotemia, and increased serum alanine aminotransferase and alkaline phosphatase activities, and increased total bilirubin.

Diagnosis of ehrlichiosis requires visualization of morulae, detection of *E. canis* antibodies, or PCR amplification of *E. canis*, *E. chaffeensis*, or *E. ewingii* DNA.[16–19] The IFA technique, dot enzyme-linked immunosorbent assay (ELISA) test, or recombinant ELISA test is available for detection of *Ehrlichia* species antibodies.[16–18] Due to cross-reactivity to immunoreactive proteins, most dogs infected with *E. canis* or *E. chaffeensis* will have positive IFA or ELISA test results, whereas less than half of the dogs infected with *E. ewingii* will have measurable cross-reacting antibodies.[12] Although interlaboratory variation in serologic results occurs due to interpretation error, the IFA test for *E. canis* is highly sensitive. Serologic cross-reaction has not been reported in association with *R. rickettsii, B. canis*, *A. platys*, or *A. phagocytophilum*. A positive titer is considered indicative of infection, because most experimentally infected dogs become seronegative within 6 to 9 months after effective treatment, whereas untreated dogs remain seropositive. Infection with *E. canis* does not infer protective immunity; therefore subsequent exposure to infected ticks after treatment will result in disease recurrence, generally of decreased severity. After antibiotic treatment some dogs become asymptomatic but maintain high *E. canis* antibody titers for years.[20] Clinically, dogs are assumed to have eliminated the infection with an *Ehrlichia* spp. if hyperglobulinemia resolves progressively after treatment or if *Ehrlichia* spp. DNA cannot be amplified from EDTA blood samples.

Infrequently, a dog maintains a high antibody titer or a hematologic abnormality such as thrombocytopenia persists for years after antibiotic therapy.[21] Although it is unclear whether these dogs are chronically infected with *E. canis*, infected with other pathogens, or if the persistent hematologic abnormalities are mediated through altered immunoregulation induced by the organism, little evidence exists to support antimicrobial resistance among *Ehrlichia* spp. that leads to persistent infection. Increasingly, PCR is becoming an important clinical diagnostic tool to differentiate the infecting *Ehrlichia* spp. and to determine if treatment has effectively eliminated the infection.[17,19] In dogs with persistently high *E. canis* antibody titers, PCR testing is indicated, preferably when antibiotics are not being administered.

Tetracycline (22 mg/kg three times a day for 21 days) or doxycycline (5 mg/kg twice a day for 21 days) are currently recommended for treatment of canine ehrlichiosis.[21,22] Experimentally, enrofloxacin will suppress the infection and may result in clinical and hematologic improvement but does not eliminate the infection.[23] Although imidocarb dipropionate has gained clinical acceptance in some endemic regions for treating severe, chronic, or presumed refractory cases of ehrlichiosis, lack of efficacy has been demonstrated in treating some dogs with ehrlichiosis.[22] Clinical improvement may be observed with penicillin or sulfonamides, but the response is variable and infection generally persists.

The short-term prognosis for canine ehrlichiosis is generally good. Dramatic clinical improvement usually occurs within 24 to 48 hours after initiation of tetracycline or doxycycline in dogs with acute-phase or mild chronic-phase disease. Following treatment, rapid clinical improvement is frequently noted in chronically infected dogs; however, periods up to a year may be necessary for complete hematologic recovery. The long-term prognosis is variable, potentially related to failure to diagnose concurrent infections.[24] Continuous or long-term administration of antibiotics, such as tetracycline, has apparently contributed to delayed hematologic recovery in dogs with obvious clinical improvement. Hemorrhage or concurrent infection may contribute to death of chronically infected dogs, despite the initiation of tetracycline therapy. The duration of doxycycline treatment for chronically affected dogs or those with severe pancytopenia or aplastic anemia remains controversial. Supportive therapy, including fluids, blood transfusion, vitamins, and anabolic steroids is required in some dogs. Long-term tetracycline prophylaxis (6.6 mg/kg once daily), repositol oxytetracycline (200 mg intramuscularly [IM] twice weekly), and topically applied acaracides have been used in military working dogs to prevent *E. canis* infection in highly endemic regions. This approach may be appropriate for recurrent infections in kennels if tick control measures are of limited effectiveness. Because of extensive dog transport and chronic asymptomatic *E. canis* infection, the establishment of new endemic foci in previously naive regions is possible. Tick control measures are very important but may not always provide an effective means to prevent infection with an *Ehrlichia* spp.[25] No vaccine is currently available.

It appears that most *Ehrlichia* spp. are capable of infecting people; however, for various reasons dogs play a seemingly minor role in the acquisition of human infections. Early reports suggested that nonhuman primates could be infected with *E. canis* and, more recently, an organism genetically related to *E. canis* was isolated from a veterinarian in Venezuela.[26] Both *E. chaffeensis* and *E. ewingii* can cause serious disease manifestations in people, including meningoencephalitis, acute renal failure, and acute respiratory failure.[27,28]

166.5 CANINE ANAPLASMOSIS

In endemic regions, *Ixodes scapularis*, *I. pacificus*, or *I. ricinus* (Europe) transmit *Anaplasma phagocytophilum* to cats, dogs, sheep, horses and human beings.[29] Numerous species of small rodents, including *Peromyscus leucopus*, the white-footed mouse, serve as reservoirs for the organism in nature.[30] Infection has also been documented in

numerous species of wild and domestic animals. California, Minnesota, Wisconsin, and several New England states (areas endemic for *I. scapularis* or *I. pacificus*) report a particularly high prevalence of infection, generally in dogs, horses, and human beings. Fever, lethargy, and a reluctance to move, accompanied by lymphopenia, thrombocytopenia, elevated serum alkaline phosphatase and amylase activities, and hypoalbuminemia are the most common clinical abnormalities reported in dogs. In the Northeast and North Central United States, acute disease occurs most frequently in the fall months during the period that adult *I. scapularis* ticks are active. Granulocytic morulae can be found within neutrophils and acute and convalescent serology is recommended to document seroconversion to *A. phagocytophilum* antigens in acutely ill dogs, cats, or horses. Infection with *A. phagocytophilum* can also be confirmed by PCR. Both ELISA and IFA tests using *E. canis* antigens will in most instances not detect cross-reacting antibodies in dogs with anaplasmosis. Therapeutically, tetracycline hydrochloride or doxycycline elicit rapid improvement in clinical status. The extent to which *A. phagocytophilum* induces chronic infection in dogs in North America is unclear; however, in Sweden, chronic infection with *A. phagocytophila* has been documented in experimentally infected dogs for up to 6 months after infection.[31] Administration of corticosteroids facilitated the detection of neutrophilic inclusions.

166.6 CANINE CYCLIC THROMBOCYTOPENIA

Canine cyclic thrombocytopenia is caused by *A. platys*, a bacterial organism that replicates only in platelets.[32,33] The mode of *A. platys* transmission is presumed to be by tick vector, but experimentally, *Rhipicephalus sanguineous*, the vector for *E. canis*, did not transmit *A. platys* infection. In the United States, *A. platys* is generally considered to be minimally pathogenic, and is usually recognized as an incidental observation during blood smear examination. The distribution of *A. platys* infection in the United States has not been established; however, most reports have originated from the South and Southeast, with occasional reports from the North and North Central portion of the country. With the exception of a single case report of uveitis, naturally occurring and experimental infections have not been associated with clinical signs. Similar to anaplasmosis in cattle, *A. platys* causes cyclic bacteremia, accompanied by thrombocytopenia, at approximately 10 to 14 day intervals. At its nadir, thrombocytopenia can be severe (20,000 to 50,000 platelets/µl), and platelets are hypoaggregatable. A mild normocytic, normochromic, nonregenerative anemia, leukopenia, hypoalbuminemia, and hyperglobulinemia, has been reported in association with experimental *A. platys* infection. On Giemsa-stained blood smears, *A. platys* appears as single or less frequently multiple basophilic inclusions within platelets. The duration of infection in untreated dogs has not been clearly established.

634

635

Diagnosis of *A. platys* requires visualization of platelet inclusions, detection of serum antibodies by indirect immunofluorescence, or PCR amplification. Sera from *A. platys*–infected dogs does not cross-react serologically with *E. canis, A. phagocytophilum*, or *N. risticii* antigens. Antibodies appear in the serum 2 to 3 weeks after experimental infection and are usually detectable during the initial thrombocytopenic episode. In a study of thrombocytopenic and healthy kennel dogs in Louisiana, seroprevalence to *A. platys* was 40.7% in the thrombocytopenic group and 54.2% in healthy kennel dogs. *Anaplasma platys* morulae were detected in only one of the thrombocytopenic dogs. These results suggest that exposure to *A. platys* in southern states is extensive, and that premunition most probably develops after several cycles of thrombocytopenia. Coinfection with *E. canis* and *A. platys* is common, and it has been theorized that *A. platys* infection might intensify the clinical course of canine ehrlichiosis.

Treatment with oral tetracycline (22 mg/kg every 8 hours for 14 days), or presumably doxycycline (5 mg/kg every 12 hours for 14 days), should eliminate the organism. Because experimental studies have not identified abnormal clinical signs associated with *A. platys* infection, caution should be exercised in ascribing clinical illness to *A. platys*. In such cases, other infectious and noninfectious causes of thrombocytopenia should be pursued diagnostically.

166.7 NEORICKETTSIA RISTICII

In 1994, Kakoma and colleagues reported serologic evidence of over 100 cases of "atypical canine ehrlichiosis" with 3 fatalities.[34] These dogs were not seroreactive to *E. canis* antigens by IFA but were reactive to *N. risticii* antigens at generally low antibody titers. *Neorickettsia risticii* is the cause of Potomac horse fever.[35] Serum samples in this study were derived from California, Texas, Arizona, Illinois, Washington, Florida, and Michigan. Isolates obtained from 3 dogs were morphologically and genetically (based on partial 16S rRNA gene sequence) indistinguishable from *N. risticii*.[34] Successful experimental transmission of a dog isolate has not been reported. Clinical abnormalities, described for 6 dogs, included lethargy, vague signs of abdominal discomfort with intermittent vomiting, persistent bleeding or petechial hemorrhages, polyarthritis, dependent edema, and posterior paralysis. Hematologic abnormalities were variably present and included anemia, thrombocytopenia, prolongation of prothrombin time (PT), and hypercalcemia. Therapy with tetracycline also appears to be variably efficacious for treatment of this infection, with substantial improvement in some dogs and a complete lack of response in other dogs. The authors propose that pending additional research, the canine isolate be referred to as *N. risticii* subsp. *atypicalis*. The definitive pathophysiologic characterization of this organism as a cause of disease in dogs awaits additional study.

166.8 FELINE EHRLICHIOSIS, ANAPLASMOSIS, AND NEORICKETTSIOES

Morulae-like inclusion bodies have been observed in monocytes, lymphocytes, or granulocytes of cats living in Kenya, France, Sweden, and the Northeastern, Midwestern and Western United States.[36–38] Antibody reactivity to *E. canis* or *N. risticii* antigens has also been reported.[38] Although the precise clinical significance of these observations awaits the results of future studies, it seems probable that cats can be infected by one or more members of the genus *Ehrlichia*, *Anaplasma*, and *Neorickettsia*. Experimentally, inoculation of cats with *A. phagocytophilum* resulted in asymptomatic infection, or mild fever and depression, and the development of neutrophilic and eosinophilic morulae. Recently, several laboratories have amplified *A. phagocytophila* DNA from the blood of acutely ill cats with fever, lethargy, inappetence, and thrombocytopenia.[37,39] These feline cases have been identified in geographic regions that are endemic for canine, equine, or human anaplasmosis.

Anorexia, loss of body condition, fever, splenomegaly, lymphadenopathy, normocytic normochromic anemia, radiographic evidence of interstitial lung disease, and mononuclear intracytoplasmic inclusions typical of the genus *Ehrlichia* were described in three cats from Kenya. Neutropenia and hyperglobulinemia were each reported in one cat. These cats were infested with *Haemaphysalis laechi* ticks. Resolution of disease signs was reported after treatment with either tetracycline hydrochloride or imidocarb dipropionate. Intracytoplasmic inclusions resembling morulae have been observed during cytologic evaluation of a lymph node aspirate from a cyclically febrile, anorexic cat from Colorado. Laboratory abnormalities included a normocytic normochromic nonregenerative anemia, hyperglobulinemia, and pyogranulomatous lymphadenitis. Serum immunoglobulin G (IgG) antibodies to *E. canis* antigen were detected, and the cat responded rapidly to doxycycline despite a previous lack of response to several other antibiotics. Serologic evidence of ehrlichiosis was reported in 12 sick cats with clinical and laboratory abnormalities including fever, malaise, weight loss, anorexia lymphadenopathy, nonseptic suppurative polyarthritis, anemia, thrombocytopenia, neutropenia, and polyclonal or monoclonal gammopathy.[36,38] Each of these cats responded favorably to doxycycline. Based upon PCR amplification and DNA sequencing, *E. canis*-like infection has been reported in cats from the United States, Canada, and France.[40,41] Consistent with previous reports, these cats had polyarthritis or bone marrow suppression accompanied by anemia, thrombocytopenia or pancytopenia. However, despite chronic illness and the detection of

antinuclear antibodies (ANAs), IFA testing using *E. canis* antigens was negative. Antibody reactivity (IFA and Western immunoblot) to *N. risticii* antigens was described in five cats from California.[38] Hematologic abnormalities included leukopenia, anemia, and thrombocytopenia. All attempts to isolate, transmit, or detect *E. risticii* by PCR were unsuccessful. Additional studies are needed to isolate and genetically characterize feline *Ehrlichia*, *Anaplasma*, and *Neorickettsia* organisms to clarify further the pathogenic importance of these organisms in cats.

166.9 COINFECTION WITH MULTIPLE TICK-TRANSMITTED PATHOGENS

Recent serologic and PCR evidence indicates that coinfection with *Ehrlichia, Babesia, Rickettsia,* and *Bartonella* spp. occurs more frequently in dogs than previously realized.[42–45] The extent to which infection with multiple organisms complicates the clinical, diagnostic, and therapeutic features that would be anticipated if a dog were infected with only one organism is not clear. In general, coinfection should be considered in dogs with unusually severe clinical presentations. For example, infection with *Bartonella* in dogs concurrently infected with *Ehrlichia canis* may contribute to the tendency to develop epistaxis. Recent observations also illustrate the difficulty in attributing causation to a single organism in dogs or people coinfected with multiple tick-transmitted pathogens.[45] As certain *Borrelia*, *Ehrlichia*, *Babesia*, and *Bartonella* spp. can cause chronic, insidious infection in dogs, the relative role of each organism to the pathogenesis of specific disease manifestations in a sick, naturally infected dog will remain difficult to establish. From an evolutionary perspective, it is obvious that vectors, vector-borne intracellular organisms, and animal and human hosts have developed a highly adapted form of interaction. In general, vectors need blood for nutrition; the bacterial, rickettsial, and protozoal organisms need an intracellular environment to survive; immunologically, most hosts appear to be able to support chronic infection with many vector-borne organisms for months to years without obvious deleterious effects. Certainly more recent evidence indicates that clinicians should screen for a panel of intracellular pathogens when dealing with sick dogs with a history of tick and flea exposure. This same evidence emphasizes the importance of strategies to control ticks and fleas on dogs and cats.

167 CHAPTER • 167 Canine Bartonellosis

Edward B. Breitschwerdt

B*artonella* species are fastidious gram-negative bacteria that are highly adapted to a mammalian reservoir host and within which the bacteria usually cause a long-lasting intraerythrocytic bacteremia.[1,2] In the natural host, chronic bacteremia with a *Bartonella* species can frequently be detected by culture or PCR in seemingly healthy individuals. Until recently, mechanisms that facilitate persistent *Bartonella* bacteremia in mammals were not well understood. Recent studies, have identified an intraerythrocytic localization for these bacteria, which is a unique strategy for bacterial persistence.[1–6] Nonhemolytic intracellular colonization of erythrocytes would preserve the organisms for efficient vector transmission, protect *Bartonella* from the host immune response, and potentially contribute to decreased antimicrobial efficacy.[3] *Bartonella* spp. are an important cause of bacillary angiomatosis, peliosis hepatis, fever of unknown origin, endocarditis, granulomatous hepatitis, and a rapidly expanding spectrum of less frequently diagnosed medical conditions in people.[7–9]

Bartonella vinsonii (*berkhoffii*) was isolated from a dog with endocarditis in 1993.[10,11] Retrospectively, long-term administration of immunosuppressive doses of corticosteroids for a presumptive diagnosis of systemic lupus erythematosus (SLE) may have facilitated the isolation of *B. vinsonii (berkhoffii)* from this dog. Subsequent attempts to isolate *B. vinsonii* from immunocompetent dogs with serologic or molecular evidence of *Bartonella* infection have not been successful in most instances. When using the currently recommended microbiologic techniques, there appears to be considerable variation in the degree of difficulty associated with the isolation of different *Bartonella* spp. from the blood of different animal species. *Bartonella vinsonii (berkhoffii)* is difficult to isolate, as compared with the relative ease of isolating *B. henselae* from the blood of infected cats. For this reason, sensitive molecular-based detection methods are proving to be diagnostically useful.

167.1 SEROPREVALENCE

Due to the relatively recent recognition that dogs can be infected with *B. vinsonii (berkhoffii)* and potentially other *Bartonella* spp., seroprevalence data is limited.[12–15] Seroprevalence was determined in 1920 sick dogs from North Carolina or surrounding states that were evaluated at a veterinary teaching hospital.[12] Using a reciprocal titer of greater than 64, 3.6% of the dogs had antibodies to *B. vinsonii (berkhoffii)*. Risk factors that could be associated with seroreactivity included heavy tick exposure (odds ratio, 14.2), cattle exposure (odds ratio, 9.3), rural versus urban environment (odds ratio, 7.1), and heavy flea exposure (odds ratio, 5.6). These data were interpreted to support the possibility that exposure to *B. vinsonii (berkhoffii)* was more likely in dogs in rural environments that were allowed to roam and were likely to have a history of heavy tick infestation. Using sera from dogs experimentally infected with *R. rickettsii* or *Ehrlichia canis*, cross reactivity to *Bartonella* antigens was not detected. However, 36% and 52% of serum samples derived from dogs naturally infected with *E. canis* or *B. canis* were reactive to *B. vinsonii* antigens. Because both *E. canis* and *B. canis* are transmitted by *Rhipicephalus sanguineous*, this tick may be involved in the transmission of *B. vinsonii*. The possibility of tick transmission was further supported by two additional studies involving dogs infected with one or more *Ehrlichia* spp. from the same geographic region, in which seroreactivity to *B. vinsonii (berkhoffii)* antigens was 30% and 89%, respectively.[16,17] Seroprevalence, using *B. vinsonii (berkhoffii)* antigens, was 10% (4 of 40 dogs) in dogs with suspected tick-borne illness from Israel and 36% in dogs with fever and thrombocytopenia from Thailand.[15,18] Using an ELISA assay, 35% of 869 samples (derived from coyotes in California) contained antibodies to *B. vinsonii (berkhoffii)* antigens.[19] These data suggest that *B. vinsonii (berkhoffii)* is distributed throughout the world.

167.2 DISEASE MANIFESTATIONS

The spectrum of disease associated with *Bartonella* infection in dogs and most other animal species is currently unknown. Endocarditis, caused by *B. vinsonii (berkhoffii)*, occurs in large breed dogs with a potential predisposition for aortic valve involvement.[10,20,21] Intermittent lameness, bone pain or fever of unknown origin (FUO) can precede the diagnosis of endocarditis by several months. Multifocal areas of severe myocardial inflammation can be found in some dogs with *B. vinsonii* endocarditis. Recently *B. vinsonii (berkhoffii)*, originally isolated from a dog, was isolated from a human endocarditis patient.[22] Considering these preliminary observations, derived from naturally infected dogs and people, the role of *Bartonella* spp. as a cause of myocarditis in companion animals deserves additional research consideration.

Bartonella-induced granulomatous lymphadenitis, involving the left submandibular lymph node, was diagnosed in a dog on the basis seroreactivity to *B. vinsonii (berkhoffii)* antigens, visualization of Warthin-Starry silver staining bacteria within the lymph node, and PCR amplification followed by Southern blot hybridization.[23] Seven days prior to enlargement of the lymph node, the owners removed an engorged tick from the left ear. This case may be illustrative of a clinical presentation that is analogous to acute bartonellosis (cat scratch disease) in people, where a scratch or bite injects the inoculum, as compared with direct inoculation by the bite of a tick.

Based on recently obtained serologic evidence in dogs, *B. vinsonii (berkhoffii)* or closely related *Bartonella* species appear to contribute to the development of dermatologic lesions indicative of a cutaneous vasculitis, anterior uveitis, polyarthritis, meningoencephalitis, and immune-mediated hemolytic anemia.[24] Thrombocytopenia is found in approximately half of the dogs with disease manifestations. Eosinophilia is also found in approximately one third of infected dogs.

Based upon current evidence, *B. vinsonii (berkhoffii)* is considered the most frequent *Bartonella* species that causes disease in dogs. However, this conclusion may not be accurate, because sera from dogs have not been screened systematically against a large panel of *Bartonella* species antigens. Studies from Hawaii, the United Kingdom, and Japan identified *B. henselae* seroprevalences of 6.5% (2 of 31 dogs), 3.0% (3 of 100 dogs), and 7.7% (4 of 52 dogs).[25–27] However, it is becoming increasingly clear that other *Bartonella* species can infect dogs. For example, *B. henselae* was amplified and sequenced on two independent occasions from the liver of a dog with peliosis hepatis.[28] This is a unique pathologic lesion that is induced only by *B. henselae* infection in people.[1,8] Recently, *B. henselae* DNA was amplified from a dog with granulomatous hepatitis, a histopathologic lesion that is reported with some frequency in children infected with *B. henselae*.[29] Similarly, *B. clarridgeae* was cultured, and DNA was amplified from the aortic valve of a dog with vegetative valvular endocarditis.[21] *Bartonella clarridgeae* was also amplified and sequenced from the liver of a Doberman pincher with copper storage disease.[29] *Bartonella elizabethae*, a species that infects rodents, was PCR amplified and sequenced from an ethylenediamine tetra-acetic acid (EDTA) blood sample obtained from a dog that had experienced chronic weight loss culminating in sudden unexplained death.[30] The clinical importance of these observations, particularly as relates to causation, is unknown. However, although presumably infrequent, *Bartonella* spp. that frequently infect cats or rodents and are transmitted by fleas among reservoir hosts, may occasionally be found in dogs with disease manifestations.

167.3 DIAGNOSTIC CONSIDERATIONS

Thrombocytopenia, anemia (which frequently can be immune-mediated), and neutrophilic leukocytosis are the most commonly detected hematologic abnormalities. Monocytosis and eosinophilia can also occur in *B. vinsonii*–infected dogs. During a 149-day study, after experimental inoculation of SPF dogs with culture grown *B. vinsonii (berkhoffii)*, there was sustained suppression of peripheral blood CD8+ lymphocytes, accompanied by an altered cell surface phenotype and an increase in CD4+ lymphocytes in the peripheral lymph nodes.[31] Therefore infection with *B. vinsonii (berkhoffii)* could induce a degree of chronic immunosuppression that might predispose to secondary infections and result in a wide array of clinical manifestations in dogs naturally infected with *Bartonella* species. Because blood culture is insensitive, serology and PCR amplification of *Bartonella* DNA are the mainstays of diagnosis. As seroprevalence to *B. vinsonii (berkhoffii)* antigens is infrequently detected (<4%) in sick dog populations in endemic regions, detection of antibodies in a sick dog provides strong clinical evidence for prior exposure and potentially active infection. For this reason, treatment of seroreactive dogs is recommended. A reciprocal titer of 64 or greater is considered indicative of prior exposure to or active infection with *B. vinsonii (berkhoffii)*. Testing against other *Bartonella* spp. antigens, such as *B. henselae,* may prove to be of clinical use in the future.

167.4 TREATMENT

To date, an optimal protocol has not been established for the treatment of *Bartonella* infections in cats, dogs, or people.[32,33] Regardless of the antibiotic used for treatment, a long duration of antibiotic administration (4 to 6 weeks) may be necessary to eliminate the infection. Macrolides (erythromycin, azithromycin) most probably represent the oral antibiotic class of choice for treating *Bartonella* infections.[32,33] Fluoroquinolones alone (or in combination with amoxicillin) have also elicited a positive therapeutic response in dogs, which is accompanied by a progressive decrease in *B. vinsonii* antibody titers.[24] Doxycycline may be effective for treatment of *B. vinsonii (berkhoffii)* in dogs, but data from cats experimentally or naturally infected with *B. henselae* or *B. clarridgeae* indicates that a high dose (10 mg/kg every 12 hours) for 4 to 6 weeks may be necessary to eliminate *Bartonella* infection in dogs, cats, or other animal species.[34] Recently, retrospective analysis of the treatment of human *Bartonella* endocarditis identified a more favorable outcome if an aminoglycoside was prescribed for a minimum of 2 weeks.[35] In those situations in which *Bartonella* infection poses serious risk in dogs, such as endocarditis, myocarditis, or meningoencephalitis, use of an aminoglycoside may be warranted.

167.5 PREVENTION

Increasingly, veterinarians play an important role in advising the public as to the epidemiologic and zoonotic implications of vector-borne pathogens. Nondomestic animals frequently serve as the primary reservoir for *Bartonella* species. For example, the coyote appears to be an important reservoir host for *B. vinsonii (berkhoffii)*.[36] Although somewhat circumstantial, increasing evidence suggests that *Bartonella* species can be transmitted by fleas and ticks to cats, dogs, or human beings.[12,23,37] Therefore minimizing or eliminating flea and tick exposure is perhaps of greater public health importance today than during any previous time. When rigorous flea and tick control measures are instituted, it is highly probable that transmission of *Bartonella* species will be greatly reduced or eliminated.[38]

168 CHAPTER • 168 Protozoal and Miscellaneous Infections

Michael R. Lappin

Multiple pathogenic protozoans infect dogs and cats. The group can be divided into amoeba, ciliates, coccidians, flagellates, Microspora, and Piroplasmia. Protozoans generally cause gastrointestinal (GI) tract disease (enteric protozoans), polysystemic disease, or in the case of *Toxoplasma gondii*, both enteric and polysystemic disease.

168.1 ENTERIC PROTOZOAL DISEASES

The most common protozoal agents infecting the GI tract of dogs and cats are *Giardia* spp., *Cryptosporidium* spp., *Cystoisospora* spp., *Sarcocystis* spp., *Besnoitia* spp., *Hammondia* spp., *T. gondii*, *Neospora caninum*, *Entamoeba histolytica*, *Balantidium coli*, and *Tritrichomonas foetus*.[1–3] *Giardia* and *T. foetus* are flagellates, *Cystoisospora* spp., *Sarcocystis* spp., *Besnoitia* spp., *Hammondia* spp., *N. caninum*, *T. gondii*, and *C. parvum* are coccidians, *B. coli* is a ciliate, and *E. histolytica* is an amoeba. *Cystoisospora* spp., *Sarcocystis* spp., *Besnoitia* spp., *Hammondia* spp., *N. caninum*, and *T. gondii* only complete the intestinal cycle in one species. Some isolates of *Cryptosporidium* spp., *Giardia* spp., *E. histolytica*, and *B. coli* will replicate in multiple warm-blooded vertebrates and therefore can potentially be zoonotic.

Fecal oral transmission occurs with all the enteric protozoans. The coccidians produce oocysts. *Cryptosporidium* spp. oocysts are immediately infectious when passed by the host; *T. gondii*, *N. caninum,* and *Cystoisospora* spp. must sporulate outside the host to be infectious. Both trophozoites and cysts of *Giardia* spp. are potentially infectious; however, transmission occurs most frequently after ingestion of cysts because gastric secretions generally kill trophozoites. Ingestion of the organism in the tissues of transport hosts can also result in infection by *Cystoisospora* spp., *Besnoitia* spp., *Hammondia* spp., *N. caninum*, and *T. gondii*. Carnivorism can result in infection by *Cryptosporidium* spp., *Giardia* spp., *E. histolytica*, and *B. coli* if the organisms are present in the intestines of the prey species. Infections can be self-limiting for each of the agents; however, with the exception of *T. gondii,* fecal shedding periods are variable. After tissue cyst ingestion, infected cats rarely shed oocysts of *T. gondii* for more than 2 weeks.[4]

The enteric protozoans have worldwide distribution. Because they are maintained in nature primarily by fecal-oral transmission, more cases are associated with crowded and unsanitary environments. In general, *Giardia* spp., *T. gondii*, *Cystoisospora*, and *Cryptosporidium* spp., *T. foetus* (cats) infections are common in the United States; *E. histolytica*, *B. coli*, and infections are rare. Antibodies against *T. gondii* (40%) and *Cryptosporidium* spp. (8.3%) are commonly detected in serum from client-owned cats, suggesting that exposure is common.[4,5] Prevalence of the agents varies by region in coprologic studies.

Pathogenic mechanisms have not been ascertained for each of the enteric protozoans. *Cystoisospora* spp. and *T. gondii* replicate in intestinal cells and may result in clinical illness from cell destruction. Tissue invasion also can occur with *E. histolytica*.[6,7] *Giardia* spp. and *Cryptosporidium* spp. are found on the surface of enterocytes, so pathogenesis is unlikely secondary to direct cell damage. Some of the pathogenic mechanisms proposed for these enteric agents include production of toxins, disruption of normal flora, induction of inflammatory bowel disease (IBD), inhibition of normal enterocyte enzymatic function, blunting of microvilli, and induction of motility disorders. *Cystoisospora* spp. generally are only pathogens resulting in clinical disease in puppies or kittens, and *Sarcocytis* spp., *Besnoitia* spp., and *Hammondia* spp. are almost never pathogenic in dogs or cats. All other enteric protozoans can cause disease regardless of age. Clinical disease is more common, and duration of organism

shedding into the environment may be prolonged in dogs and cats with immunodeficiency inducing concurrent diseases.

Owner concerns in dogs or cats with enteric protozoal infections generally are vomiting, inappetence, or diarrhea; fever is uncommon. *Giardia* spp., *Cryptosporidium* spp., and *T. gondii* infections are most commonly associated with small-bowel diarrhea; *E. histolytica*, *B. coli*, and *T. foetus* infections are most commonly associated with large-bowel diarrhea. *Cystoisospora* spp. infections can cause clinical signs of large or small-bowel diarrhea. Physical examination findings in dogs or cats with enteric protozoal infections are nonspecific but can include abdominal discomfort, increased gas or fluid in the intestinal tract, or thickened intestinal loops.

All dogs and cats with large, small, or mixed bowel diarrhea should be assessed for enteric protozoal infections. Diagnosis of GI protozoal infection is based primarily on documentation of oocysts, trophozoites, or cysts on direct fecal examination or fecal flotation.

A direct smear of diarrheic stool can be used to examine for trophozoites of *E. histolytica*, *B. coli*, *T. foetus*, or *Giardia*. More frequently, a small quantity of fresh feces or mucous is mixed with a drop of 0.9% NaCl on a clean microscope slide and examined at 100X after placing a cover slip. When a motile organism is noted, examining at 400X assesses structural features. Application of a stain like Lugol's solution, methylene blue, or acid methyl green to the wet mount at the edge of the cover slip will aid in visualizing internal structures of protozoa.[8] Trophozoites are rarely found in formed stools. Duodenal aspiration for cytologic examination for *Giardia* trophozoites is effective for the diagnosis of giardiasis in the dog. However, this technique is not effective in the cat because the organism lives in the distal small intestine.

Protozoal cysts or oocysts are best demonstrated after fecal concentration; Sheather's sugar centrifugation and zinc sulfate centrifugation are two techniques commonly used in clinical practice.[8] These solutions are inexpensive and generally effective. Sugar solution is hypertonic and will distort *Giardia* spp. cysts; the cytoplasm is pulled to one side and appears as a half-or quarter-moon. Zinc sulfate centrifugation is considered by some to be the flotation solution of choice for *Giardia* spp. cysts.

Due to small size and limited number in feces of infected dogs and cats, *Cryptosporidium* spp. oocysts are almost never seen when concentrated feces are examined at 100X. Acid-fast staining or fluorescein-labeled monoclonal antibody staining of a fecal smear and fecal antigen testing can aid in the diagnosis of cryptosporidiosis in dogs and cats. Oocysts stain pink with acid-fast stain. A fluorescein-labeled monoclonal antibody system is also available for identification of *Giardia* spp. cysts. Antigens of *Giardia* spp. and *Cryptosporidium* spp. can be detected in feces by enzyme-linked immunosorbent assay (ELISA). However, it is now known that dog-and cat-specific *Giardia* spp. and *Cryptosporidium* spp. exist[9–12]; most currently available tests were titrated using isolates from human feces. A *Gardia* spp. antigen ELISA for veterinary use is currently being evaluated (IDEXX Laboratories, Portland, ME). Thus results of indirect fluorescent antibody (IFA) and antigen assays should be interpreted with results from fecal examination techniques. Polymerase chain reaction (PCR) assays for demonstration of *Giardia* spp., *Cryptosporidium* spp., and *T. foetus* DNA in feces are being studied. In addition, *T. foetus* can be cultured from feces.

638
639

The presence of enteric protozoans in diarrheic stool does not prove that disease was due to the organism. Some enteric protozoans, especially *Giardia* spp., *Cryptosporidium* spp., *T. foetus*, and *Cystoisospora* spp. live chronically in the intestinal tract of normal animals; other conditions causing GI tract disease can induce shedding. Thus animals with enteric protozoal infections that do not respond to therapy should be evaluated for underlying causes of disease. *Giardia* spp., *Cryptosporidium* spp., *Cystoisospora* spp., and *Sarcocystis* spp. are commonly found in animals with normal stools; therefore yearly fecal examinations are indicated in all dogs and cats.

Withholding food for 24 to 48 hours is indicated for animals with acute vomiting or diarrhea. Highly digestible, bland diets are used most frequently if vomiting and small-bowel diarrhea are the primary manifestations of disease. High-fiber diets are generally indicated if large-bowel diarrhea is occurring. Feeding a high-fiber diet may also aid in the treatment of giardiasis due to inhibition of trophozoite attachment to duodenal epithelial cells.

Dogs and cats with *Giardia* spp. infections generally respond clinically to the administration of metronidazole, but infection may not be cleared; this drug may also be effective for dogs infected with *E. histolytica* (Table 168-1). Because dogs or cats with giardiasis could also be infected with these other potentially zoonotic enteric protozoans, metronidazole is a logical primary drug. Metronidazole also helps correct the anaerobic bacterial overgrowth that commonly accompanies giardiasis. If inflammatory changes exist, metronidazole may also be beneficial due to inhibition of lymphocyte function. In a recent study of cats, administration of liquefied metronidazole benzoate for 7 days was 100% effective during the time period studied.[13] Central nervous system (CNS) toxicity occasionally occurs with this drug; it is unlikely if no more than 50 mg/kg is given orally per day.[14,15] Fenbendazole and albendazole are commonly prescribed alternate anti-*Giardia* spp. drugs; albendazole is associated with neutropenia in dogs and cats and so should not be used.[16–19] Furazolidone (cats); paromomycin (dogs or cats); and febantel, pyrantel, and praziquantel (dogs) are other drugs with anti-*Giardia* effects.[20] Lastly, use of the commercially available *Giardia* spp. vaccines as immunotherapy has given variable treatment responses.[21–23] Cats with concurrent diarrhea and *T. foetus* infection will sometimes respond clinically to administration of metronidazole, fenbendazole, or tylosin; however, none of these drugs have eliminated the infection. Cats that fail to respond immediately to treatment often have resolution of diarrhea in approximately 9 months.

Paromomycin, tylosin, and azithromycin have all been used to lessen diarrhea in dogs and cats with cryptosporidiosis, but no treatment has consistently stopped *Cryptosporidium* spp. oocyst shedding.[24,25] The most commonly prescribed drugs to treat *Cystoisospora* spp. infections of dogs and cats are trimethoprim-sulfonamide, sulfadimethoxine, furazolidone, amprolium, or amprolium-sulfadimethoxine. Quinacrine, spiramycin, toltrazuril, and roxithromycin have been used on a limited basis. However, no drug eliminates infection.

Cryptosporidium spp., *T. gondii*, *Giardia*, *E. histolytica*, and *B. coli* are potentially zoonotic. *Entamoeba histolytica* and *B. coli* infections are extremely uncommon, and pets are unlikely sources of human infections. Most people are infected with *Cryptosporidium* spp. or *Giardia* spp. from contaminated food or water, not contact with pets.[26–28] It is now known that *Cryptosporidium* spp. and *Giardia* spp. exist that are specific to people or pets. For example, in one recent study of *C. hominis* of people, the organism failed to infect dogs and cats.[29] In one enzootic area, people were infected with a human *Giardia* and dogs were infected with a dog *Giardia*; cross-infection did not seem to occur.[11] Thus not all *Cryptosporidium* spp. and *Giardia* spp. are zoonotic. However, it is impossible to determine clinically if an individual strain is infectious to people; therefore infected animals should be managed as a potential zoonotic risk. (See the following section for a discussion of *T. gondii* associated zoonotic disease.)

168.2 POLYSYSTEMIC PROTOZOAL DISEASES

The primary protozoans that induce polysystemic disease in dogs and cats are *Acanthomoeba* spp., *Hepatozoon canis*, *Neospora caninum*, *Toxoplasma gondii*, *Leishmania* spp., *Trypanosoma cruzi*, *Cytauxzoon felis*, *Babesia* spp., and *Pneumocystis carinii*.

168.3 COCCIDIANS

168.3.1 Toxoplasmosis

Toxoplasma gondii is one of the most prevalent parasites infecting warm-blooded vertebrates.[4] Only cats complete the coccidian life cycle and pass environmentally resistant oocysts in feces. Dogs can pass oocysts in feces after the ingestion of feline feces.[30] Sporozoites develop in oocysts after 1 to 5 days of exposure to oxygen and appropriate environmental temperature and humidity. Tachyzoites disseminate in blood or lymph during active infection and replicate intracellularly rapidly until the cell is destroyed. Bradyzoites are the slowly dividing, persistent, tissue stage that form in the extraintestinal tissues of infected hosts as immune responses attenuate tachyzoite replication. Tissue cysts form readily in the CNS, muscles, and visceral organs.[4] Infection of warm-blooded vertebrates occurs after ingestion of any of the three life stages of the organism or transplacentally. Most cats are not coprophagic and are usually infected by ingesting *T. gondii* bradyzoites during carnivorous feeding; oocysts are shed in feces from 3 to 21 days. Sporulated oocysts can survive in the environment for months to years and are resistant to most disinfectants. Bradyzoites may persist in tissues for the life of the host. Approximately 30% to 40% of cats and people and 20% of the dogs in the United States are seropositive and therefore presumed to be infected.[4] Prior to 1988 many of the dogs diagnosed with toxoplasmosis based on histologic evaluation were truly infected with *Neospora caninum* (see Neosporosis section).[31]

Clinical disease associated with the intestinal phase of infection is rare. Approximately 10% to 20% of experimentally inoculated cats develop self-limiting, small-bowel diarrhea after primary oral inoculation with *T. gondii* tissue cysts. Detection of *T. gondii* oocysts in feces is rarely reported in studies of naturally exposed cats with diarrhea.

Death in dogs and cats can develop from overwhelming intracellular replication of tachyzoites after primary infection; hepatic, pulmonary, CNS, and pancreatic tissues are commonly involved.[32,33] Transplacentally or lactationally infected kittens develop the most severe signs of extraintestinal toxoplasmosis and generally die of pulmonary or hepatic disease.[34,35]

Common clinical findings in cats with disseminated toxoplasmosis include depression, anorexia, fever followed by hypothermia, peritoneal effusion, icterus, and dyspnea.[32] If a host with chronic toxoplasmosis is immunosuppressed, bradyzoites in tissue cysts can replicate rapidly and disseminate again as tachyzoites. Disseminated toxoplasmosis has been documented in cats concurrently infected with feline leukemia virus (FeLV), feline immunodeficiency virus (FIV), feline infectious peritonitis (FIP) virus, and after renal transplantation.[4]

Table • 168-1 Drugs Used in the Management of Protozoal and Miscellaneous Diseases

ORGANISM/DRUG NAME	COMMON CANINE DOSE	COMMON FELINE DOSE
Babesia spp.		
Clindamycin hydrochloride	12.5 mg/kg, q12h, for 14 days, PO	NA
Imidocarb dipropionate	5–6.6 mg/kg, q14 days, SC or IM	NA
Metronidazole	25 mg/kg, q8-12h, for 14 days PO	NA
Pentamidine isethionate	15 mg/kg, q24h, daily for 2 days, SC	NA
Balantidium coli		
Metronidazole	10–25 mg/kg, q12h, for 8 days, PO	NA
Tetracycline	22 mg/kg, q8h, for 7–10 days, PO	NA
Cryptosporidium spp.	Unknown	10 mg/kg, q24h, for 7–21 days, PO
Azithromycin	As for cats	10 mg/kg, q24h, for 7–21 days, PO
Paromomycin	As for cats	150 mg/kg, q12-24h, for 5 days, PO
Tylosin	As for cats	10–15 mg/kg, q12h, for 21 days, PO
Cystoisospora spp.		
Trimethoprim-sulfonamide	15–30 mg/kg, q12h, for 5 days, PO	15 mg/kg, q12h, for 5 days, PO
Sulfadimethoxine	50–60 mg/kg, daily, for 5–20 days, PO	50–60 mg/kg, daily, for 5–20 days, PO
Furazolidone	8–20 mg/kg, q12-24h, for 5 days, PO	8–20 mg/kg, q12-24h, for 5 days, PO
Amprolium	300–400 mg, daily, for 5 days	60–100 mg, daily, for 5 days
Paromomycin	As for cats	165 mg/kg, q12h, for 5 days, PO
Cytauxzoon felis		
Buparvaquone	NA	10 mg/kg, q24h, IM or SC
Diminazene	NA	2 mg/kg, q14 days, IM
Imidocarb	NA	2 mg/kg, q14 days, IM
Parvaquone	NA	10–30 mg/kg, q24h, IM or SC
Entamoeba histolytica		
Metronidazole	10–25 mg/kg, q12h, for 8 days, PO	25 mg/kg, q12h, for 7 days, PO
Giardia spp.		
Fenbendazole	50 mg/kg, q24h, for 3–7 days, PO	50 mg/kg, q24h, for 3–7 days, PO
Giardia vaccine	1 dose, q21days, for 2–3 inoculations	1 dose, q21days, for 2–3 inoculations
Metronidazole	10–25 mg/kg, q12h, for 8 days, PO	25 mg/kg, q12h, for 7 days, PO
Praziquantel, pyrantel and febantel	Daily PO for 3 days	NA
Hepatozoon americanum		
Clindamycin*	10 mg/kg, q8h, for 2–4 weeks, PO	NA
Decoquinate*	10 to 20 mg/kg, q12h, for life, PO	NA
Pyrimethamine*	0.25 mg/kg, q24h, for 2–4 weeks, PO	NA
Trimethoprim-sulfadiazine*	15 mg/kg, q12h, for 2–4 weeks, PO	NA
Imidocarb dipropionate	5–6 mg/kg, q14 days, IM or SQ	NA
Leishmania spp.		
Allopurinol	15 mg/kg, q12h, for months, PO	NA
Amphotericin B	3.0–3.3 mg/kg, q48h, 3–5 times, IV	NA
Meglumine antimonite	100 mg/kg, q24h, IV, IM, SC	NA
Sodium stibogluconate	30–50 mg/kg, q24h, IV, SC	
Neospora caninum		
Clindamycin*	10 mg/kg, q8h, for 4 weeks, PO	NA
Pyrimethamine*	1 mg/kg, q24h, for 4 weeks, PO	NA
Trimethoprim-sulfadiazine*	15 mg/kg, q12h, for 4 weeks, PO	NA
Pneumocystis carinii		
Pentamidine isethionate	4 mg/kg, q24h, for 2 weeks, IM	NA
Trimethoprim-sulfonamide	15–30 mg/kg, q8-12h, for 2 weeks, PO	NA

Tritrichomonas foetus		
Metronidazole	10–25 mg/kg, q12h, for 8 days, PO	25 mg/kg, q12h, for 7 days, PO
Toxoplasma gondii		
Azithromycin	5–10 mg/kg, q12h, for 5–7 days, PO	7–15 mg/kg, q12h, for 5–7 days, PO
Clindamycin hydrochloride	12.5 mg/kg, q12h, for 28 days, PO, IM	12.5 mg/kg, q12h, for 28 days PO, IM
Pyrimethamine	0.25–0.5 mg/kg, q24h, for 28 days PO	Usually not used due to toxicity
Trimethoprim-sulfonamide	15 mg/kg, q12h, for 28 days, PO	15 mg/kg, q12h, for 28 days, PO

IM, Intramuscular; *IV*, intravenous; *SC*, subcutaneous; *PO*, oral; *NA*, not applicable.

* Used in combination.

Chronic toxoplasmosis occurs in some dogs and cats. *Toxoplasma gondii* infection should be on the differential diagnoses list for cats with anterior or posterior uveitis, fever, muscle hyperesthesia, weight loss, anorexia, seizures, ataxia, icterus, diarrhea, and pancreatitis.[4,36] Based on results of *T. gondii*–specific aqueous humor antibody and PCR studies, toxoplasmosis appears to be a common infectious cause of uveitis in cats.[37,38] Kittens infected transplacentally or lactationally commonly develop ocular disease.[39] Immune complex formation and deposition in tissues and delayed hypersensitivity reactions may be involved in chronic, subfatal clinical toxoplasmosis. Because none of the anti-*Toxoplasma* drugs totally clear the body of the organism, recurrence of disease is common.

In dogs, respiratory, GI, or neuromuscular infection resulting in fever, vomiting, diarrhea, dyspnea, and icterus are most common and occur most frequently in immune-suppressed dogs, such as those with canine distemper virus (CDV) infection or those receiving cyclosporine to prevent rejection of a transplanted kidney.[4,40,41] Neurologic signs are dependent on the location of the primary lesions and include ataxia, seizures, tremors, cranial nerve deficits, paresis, and paralysis. Dogs with myositis have weakness, stiff gait, or muscle wasting. Rapid progression to tetraparesis and paralysis with lower motor neuron dysfunction can occur. Some dogs with suspected neuromuscular toxoplasmosis probably had neosporosis.[31] Myocardial infection resulting in ventricular arrhythmias occurs in some infected dogs. Dyspnea, vomiting, or diarrhea occur in dogs with polysystemic disease. Retinitis, anterior uveitis, iridocyclitis, and optic neuritis occur in some dogs with toxoplasmosis but are less common than in the cat.

Dogs or cats with clinical toxoplasmosis can have a variety of clinicopathologic and radiographic abnormalities but none document the disease. Nonregenerative anemia, neutrophilic leukocytosis, lymphocytosis, monocytosis, neutropenia, eosinophilia, proteinuria, bilirubinuria, increases in serum proteins and bilirubin concentration, as well as creatinine kinase, alanine aminotransferase, alkaline phosphatase, and lipase activity occurs in some animals.[4] Pulmonary toxoplasmosis most commonly causes diffuse interstitial to alveolar patterns or pleural effusion.[42] Cerebrospinal fluid (CSF) protein concentrations and cell counts are often higher than normal. The predominant white blood cells (WBCs) in CSF are small mononuclear cells, but neutrophils also are commonly found.

The antemortem definitive diagnosis of toxoplasmosis can be made if the organism is demonstrated; however, this is uncommon. Bradyzoites or tachyzoites are rarely detected in tissues, effusions, bronchoalveolar lavage fluids, aqueous humor, or CSF. Detection of 10 × 12 μm oocysts in feces in cats with diarrhea suggests toxoplasmosis but is not definitive, because *Besnoitia* and *Hammondia* infections of cats produce morphologically similar oocysts.

Toxoplasma gondii–specific antibodies (dogs or cats), antigens (cats), immune complexes (cats), and DNA (cats) can be detected in the blood of normal animals, as well as in those with clinical signs of disease; therefore it is impossible to make an antemortem diagnosis of clinical toxoplasmosis based on these tests alone.[4,37,38,43]

Of the serum tests, IgM correlates the best with clinical toxoplasmosis because this antibody class is rarely detected in serum of healthy animals. The antemortem diagnosis of clinical toxoplasmosis can be tentatively based on the combination of the following:

- Demonstration of antibodies in serum that documents exposure to *T. gondii*
- Demonstration of an IgM titer greater than 1:64 or a fourfold or greater increase in IgG titer that suggests recent or active infection
- Clinical signs of disease referable to toxoplasmosis
- Exclusion of other common causes of the clinical syndrome
- Positive response to appropriate treatment

Some animals with clinical toxoplasmosis will have reached their maximal IgG titer or will have undergone antibody class shift from IgM to IgG by the time they are serologically evaluated, so the failure to document an increasing IgG titer or a positive IgM titer does not exclude the diagnosis of clinical toxoplasmosis. Because some healthy animals have extremely high serum antibody titers and some clinically ill animals have low serum antibody titers, the magnitude of titer is relatively unimportant in the clinical diagnosis of toxoplasmosis. Because the organism cannot be cleared from the body, most animals will be antibody-positive for life; therefore repeating serum antibody titers after clinical disease has resolved is of little use.

The combination of aqueous humor or CSF *T. gondii*–specific antibody detection and organism DNA detection by PCR is the most accurate way to diagnose ocular or CNS toxoplasmosis in cats (Diagnostic Laboratory, College of Veterinary Medicine and Biomedical Sciences, Colorado State University, Fort Collins, CO 80523). Although *T. gondii*–specific IgA, IgG, and organism DNA can be detected in aqueous humor and CSF of both normal and clinically ill cats, *T. gondii*–specific IgM has only been detected in the aqueous humor or CSF of clinically ill cats and so may be the best indicator of clinical disease. Because *T. gondii* DNA can be detected in blood of healthy cats, positive PCR results do not correlate to clinical disease.

Supportive care should be instituted as needed. Clindamycin hydrochloride, trimethoprim-sulfonamide combination, and azithromycin have been used successfully for the treatment of clinical toxoplasmosis.[4,36] Pyrimethamine combined with sulfa drugs is effective for the treatment of human toxoplasmosis but commonly results in toxicity in cats. Cats or dogs with uveitis should be treated with topical, oral, or parenteral glucocorticoids to avoid secondary glaucoma and lens luxations.[4,44] *T. gondii* seropositive animals with uveitis that are otherwise normal can be treated with topical glucocorticoids alone, unless the uveitis is recurrent or persistent. In these situations, administration of a drug with anti-*T. gondii* activity may be beneficial.

T. gondii is a significant zoonosis. Primary infection of mothers during gestation can lead to clinical toxoplasmosis in the fetus; stillbirth, CNS disease, and ocular disease are common clinical manifestations. Primary infection in immunocompetent individuals results in self-limiting fever, malaise, and lymphadenopathy. As T-helper cell counts decline, approximately 10% of people with acquired immunodeficiency syndrome (AIDS) develop toxoplasmic encephalitis from activation of bradyzoites in tissue cysts. People most commonly acquire toxoplasmosis by ingesting sporulated oocysts, tissue cysts, or they acquire it transplacentally. To prevent toxoplasmosis, eating undercooked meats or ingesting sporulated oocysts should be avoided. Although owning a pet cat was epidemiologically associated with acquiring toxoplasmosis in one study of pregnant women,[45] touching individual cats is probably not a common way to acquire toxoplasmosis for the following reasons:

- Cats generally only shed oocysts for days to several weeks after primary inoculation.
- Repeat oocyst shedding is rare, even in cats receiving glucocorticoids, and in those infected with FIV or FeLV.[46,47]
- Cats with toxoplasmosis inoculated with tissue cysts 16 months after primary inoculation did not shed oocysts.[47]

641

642

- Cats are fastidious and usually do not allow feces to remain on their skin for time periods long enough to lead to oocyst sporulation; the organism was not isolated from the fur of cats shedding millions of oocysts 7 days previously.[48]
- Increased risk of acquired toxoplasmosis was not associated with cat ownership in human immunodeficiency virus (HIV)-infected people or in veterinary health care providers.[49]

If infection is suspected on fecal examination, the oocyst shedding period can be shortened by administration of clindamycin (25 to 50 mg/kg a day orally), sulfonamides (100 mg/kg a day orally), or pyrimethamine (2.0 mg/kg a day orally).[4] Because humans are not commonly infected with *T. gondii* from contact with individual cats, testing healthy cats for toxoplasmosis is not recommended. No serologic assay accurately predicts when a cat shed *T. gondii* oocysts in the past, and most cats that are shedding oocysts are seronegative. Most seropositive cats have completed the oocyst shedding period and are unlikely to repeat shedding; most seronegative cats would shed the organism if infected. If owners are concerned that they may have toxoplasmosis, they should see their doctor for testing. Avoiding sporulated oocysts and tissue cysts in undercooked meat can lessen the risk of acquiring toxoplasmosis.

168.4 NEOSPOROSIS

Neospora caninum is a coccidian previously confused with *T. gondii* due to similar morphology.[31,50,51] The sexual cycle is completed in the GI tract of dogs and results in the passage of oocysts in feces.[52–55] Sporozoites develop in oocysts within 24 hours of passage. Tachyzoites (rapidly-dividing stage) and tissue cysts containing hundreds of bradyzoites (slowly-dividing stage) are the other two life stages. Dogs are infected by ingestion of bradyzoites but not tachyzoites.[53] Infection has been documented after ingestion of infected bovine placental tissue. Transplacental infection has been well documented; dams that give birth to infected offspring can repeat transplacental infection during subsequent pregnancies.[56] Although organism replication occurs in many tissues, clinical illness primarily reflects neuromuscular infection in dogs. Although encephalomyelitis and myositis develops in experimentally infected kittens, clinical disease in naturally infected cats has not been reported.[57] Canine neosporosis has been reported in many countries around the world. Whether other intermediate hosts play a role in maintenance of infection is unknown, but white-tailed deer are commonly seropositive.[58] Because repeated transplacental infections occur, increased risk exists for puppies from a bitch that has previously birthed infected puppies.

Congenitally infected puppies develop ascending paralysis with hyperextension of the hindlimbs; muscle atrophy occurs in many cases. Polymyositis and multifocal CNS disease can occur alone or in combination. Clinical signs can be evident soon after birth or may be delayed for several weeks. Neonatal death is common. Although disease tends to be most severe in congenitally infected puppies, dogs as old as 15 years have been clinically affected. In

some dogs, myocarditis, dysphagia, ulcerative dermatitis, pneumonia, and hepatitis occur.[59–63] Glucocorticoid treatment may activate bradyzoites in tissue cysts resulting in clinical illness. CNS inflammation is usually with mononuclear cell infiltrates, which suggests an immune-mediated component to the pathogenesis of disease. If not treated, most affected dogs die.

No specific hematologic or biochemical findings exist, but increased creatine kinase (CK) and aspartate transaminase (AST) activities are common in dogs with myositis. CSF abnormalities include increased protein concentration (20 to 50 mg/dL) and a mild, mixed inflammatory cell pleocytosis (10 to 50 cells/dL) consisting of monocytes, lymphocytes, neutrophils, and rarely, eosinophils. Interstitial and alveolar patterns can be noted on thoracic radiographs. Demonstration of the organism in CSF or tissues gives a definitive diagnosis. Tachyzoites are rarely identified on cytologic examination of CSF, imprints of dermatologic lesions, and bronchoalveolar lavage. Mixed inflammation with neutrophils, lymphocytes, eosinophils, plasma cells, macrophages, and tachyzoites was noted on transthoracic aspirate of one dog with lung disease.[63]

Oocysts can be detected in feces by microscopic examination after flotation or by PCR. *Neospora caninum* tissue cysts have a wall greater than 1 μm; *T. gondii* tissue cysts have a wall less than 1 μm. The organism can be differentiated from *T. gondii* by electron microscopy, immunohistochemistry, and PCR.[61]

The clinician can make a presumptive diagnosis of neosporosis by combining appropriate clinical signs of disease and positive serology or presence of antibodies in CSF with the exclusion of other causes inducing similar clinical syndromes, in particular, *T. gondii*. Immunoglobulin G antibody titers greater than or equal to 1:200 have been detected in most dogs with clinical neosporosis; minimal serologic cross-reactivity with *T. gondii* occurs at titers greater than or equal to 1:50.

The prognosis for dogs with severe neurologic involvement is grave. Some have survived after treatment with trimethoprim-sulfadiazine combined with pyrimethamine, sequential treatment with clindamycin hydrochloride, trimethoprim-sulfadiazine, and pyrimethamine, or clindamycin alone.[59–62]

Neospora caninum antibodies have been detected in people,[64] but in one study there was no link to repeated abortion.[65] There has been an epidemiologic link between dogs and cattle; therefore efforts should be made to lessen dog fecal contamination of livestock feed, and dogs should not be allowed to ingest bovine placentas.[66] White-tailed deer are commonly seropositive, so it is possible that intermediate hosts play a role in canine infection. Bitches that whelp clinically affected puppies should not be bred. Glucocorticoids should not be administered to seropositive animals, if possible, because a potential exists for activation of infection.

168.5 HEPATOZOONOSIS

Hepatozoonosis in dogs is caused by *Hepatozoon canis* and *H. americanum*.[67,68] In North America, *H. americanum* predominates, is transmitted by *Amblyomma maculatum*, and is most common in the Texas Gulf Coast, Mississippi, Alabama, Georgia, Florida, Louisiana, and Oklahoma.[69] In Africa, southern Europe, and Asia, *H. canis* predominates and is transmitted by *Rhipicephalus sanguineous*. A *Hepatozoon* species is occasionally found in the blood of cats in Europe.[71–73] The tick ingests the organism from infected dogs during a blood meal and oocysts develop. After a dog ingests an infected tick, sporozoites are released and infect mononuclear phagocytes and endothelial cells of the spleen, liver, muscle, lungs, and bone marrow, and they ultimately form cysts containing macromeronts and micromeronts. Clinical disease results from pyogranulomatous inflammation; glomerulonephritis or amyloidosis may occur secondary to chronic inflammation and immune complex disease.

H. americanum has resulted in illness in all age groups, but disease is most commonly recognized in puppies.[73–74] Fever, weight loss, and severe hyperesthesia over the paraspinal regions are common findings. Anorexia, pale mucous membranes from anemia, depression, oculonasal discharge, and bloody diarrhea occur in some dogs. Clinical signs can be intermittent and recurrent. Clinical disease associations are currently unclear, but the cats are commonly coinfected with FeLV or FIV.

642

643

Neutrophilic leukocytosis (20,000 to 200,000 cells/μL) with a left shift is the most common hematologic finding. Thrombocytopenia is unusual unless coinfection by *Ehrlichia canis* occurs. Normocytic, normochromic nonregenerative anemia is common and is likely from chronic inflammation. Increased activity of alkaline phosphatase but not creatine kinase occur in *H. americanum* infected dogs. Hypoalbuminemia, hypoglycemia, and rarely, polyclonal gammopathy occur in some dogs. Periosteal reactions from the inflammatory reaction directed at tissue phases in muscle can occur in any bone excluding the skull, are most common in young dogs, do not occur in every case, and are not pathognomonic for hepatozoonosis. Presence of serum antibodies against *H. americanum* were compared with tissue biopsy; the sensitivity and specificity were 93% and 96%, respectively.[75] Definitive diagnosis is based on identification of gamonts in neutrophils or monocytes in Giemsa-or Leishman's-stained blood smears or by demonstration of the organism in muscle biopsy sections.

For treatment of *H. americanum*, the combination of trimethoprim-sulfadiazine, pyrimethamine, and clindamycin for 14 days is successful in the short-term.[73,74] Administration of decoquinate mixed with food lessens the likelihood of recurrence of clinical disease and prolongs survival time. Imidocarb dipropionate is the drug of choice for treatment of *H. canis* and may also be effective for *H. americanum*. Administration of nonsteroidal anti-inflammatory drugs (NSAIDs) may lessen discomfort for some dogs. No therapeutic regimen has been shown to eliminate *H. canis* or *H. americanum* infection from tissues.

Tick control is the best form of prevention. Glucocorticoid administration should be avoided because it may exacerbate clinical disease. No evidence exists for zoonotic transfer of *H. americanum* or *H. canis* from infected dogs to people.

168.6 PIROPLASMIA

168.6.1 Babesiosis

Multiple *Babesia* spp. infect dogs throughout the world.[76–85] *Babesia canis* has worldwide distribution including Africa, Asia, Australia, Europe, Central America, South America, Japan, and the United States. *B. canis rossi* is transmitted by *Haemaphysalis leachi* and is the most pathogenic. *B. canis canis* is transmitted by *Dermacenter reticulatus* and is moderately pathogenic. *B. canis vogeli* is the least pathogenic and is transmitted by *Rhipicephalus sanguineus. Babesia gibsoni* infects dogs in the United States, Japan, India, Sri Lanka, Korea, Malaysia, and Egypt. North American and Asian isolates of *B. gibsoni* vary genetically enough to be proposed as different species.[81] In countries other than the United States, *H. bispinosa* and *H. longicornis* are known vectors for *B. gibsoni. R. sanguineus* is proposed but not proven to be a vector in the United States. A *Babesia* spp. that genetically varies considerably from other *B. canis* or *B. gibsoni* isolates was described in Oklahoma. None of the *Babesia* spp. that infect cats—*B. cati* (India), *B. felis* (South Africa and Sudan), *B. herpailuri* (South America and Africa), or *B. pantherae* (Kenya)—are found in the United States.[85] *Babesia* spp. can also be transmitted by blood transfusion.

The organisms replicate intracellularly in red blood cells (RBCs) resulting in intravascular hemolytic anemia. Immune-mediated reactions against the parasite or altered self-antigens worsens the hemolytic anemia and commonly results in positive Coombs' test. Severity of disease depends on the species and strain of *Babesia* and the host immune status; chronic, subclinical infection can occur. Peracute or acute *Babesia* infections result in anemia and fever leading to pale mucous membranes, tachycardia, tachypnea, depression, anorexia, and weakness. Icterus, petechiation, azotemia, and hepatosplenomegaly are present in some dogs depending on the stage of infection and the presence of disseminated intravascular coagulation (DIC).[83–88] Severe, acute anemia potentiates the development of DIC, metabolic acidosis, and renal disease. The primary differential diagnosis for acute babesiosis is primary immune-mediated hemolytic anemia. Chronically infected dogs commonly have weight loss and anorexia. Ascites, GI signs, CNS disease, edema, and clinical evidence of cardiopulmonary disease occur in some dogs with atypical infection. Subclinical infection occurs as well. Administration of glucocorticoids or splenectomy may activate chronic disease.

Regenerative anemia, hyperbilirubinemia, bilirubinuria, hemoglobinuria, thrombocytopenia, metabolic acidosis, azotemia, polyclonal gammopathy, and renal casts are common in dogs infected with babesiosis. IFA tests for *B. canis* and *B. gibsoni* are available commercially. Demonstration of increasing titers over 2 to 3 weeks are consistent with recent or active infection. Currently no standardization exists between laboratories; therefore suggested positive “cutoff” titers vary. False-negative serologic test results can occur in peracute conditions or in dogs with concurrent immunosuppression. A titer of greater than 1:320 was suggested for *B. gibsoni*, but not all infected dogs achieve titers of this magnitude.[83] A presumptive diagnosis can be based on historical findings, physical examination findings, test results, and positive serology. Many dogs are seropositive but clinically normal; therefore serology alone cannot be used to make a definitive diagnosis.[89,90] Definitive diagnosis is based on organism demonstration in RBCs using Wright's or Giemsa stains on thin blood smears. *B. canis* is typically found as paired, piriform bodies measuring 2.4 × 5.0 μm. *B. gibsoni* is typically found as single, annular bodies measuring 1.0 × 3.2 μm. PCR is now available commercially and can be used to document organism presence, but positive results do not always correlate to clinical illness.[91]

Supportive care should be administered as indicated. Phenamidine isethionate and imidocarb dipropionate may be effective for the treatment of babesiosis.[83–88,92] Adverse effects include transient salivation, diarrhea, dyspnea, lacrimation, and depression. Metronidazole or clindamycin hydrochloride may lessen clinical disease if other drugs are not available. Diminazene aceturate, pentamidine isethionate, parvaquone, and niridazone have also been used. No drugs are available to eliminate infection; therefore it is unknown whether it is beneficial to treat healthy, seropositive dogs.

Ticks should be controlled if possible. Administration of immunosuppressive drugs and splenectomy should be avoided in previously infected dogs. Dogs used as blood donors should be assessed for infection by PCR or serologic screening. Currently no evidence exists to suggest that *Babesia* spp. infecting dogs and cats can cause human disease.

168.7 CYTAUXZOONOSIS

Cytauxzoon felis infects cats in the southeastern and south central United States. Bobcats are usually subclinically affected and are the likely natural host of the organism. The organism can be passed experimentally from infected bobcats to domestic cats by *Dermacentor variabilis*; clinical illness occurs after an incubation period of 5 to 20 days.[93] Infected macrophages line the lumen of veins throughout the body and merozoites released from the

infected macrophages infect erythrocytes. Clinical disease results from obstruction of blood flow through tissues by mononuclear infiltrates and from hemolytic anemia.

643 644

Most cases of cytauxzoonosis are in cats allowed to go outdoors. Fever, anorexia, dyspnea, depression, icterus, pale mucous membranes, and death are the most common clinical findings.[94–96] A primary differential diagnosis is haemobartonellosis. Ticks are generally not identified on affected cats. Recently, cytauxzoonosis was described in cats of Oklahoma and Arkansas that did not result in death suggesting that variants that are less virulent to cats exist.[97,98]

Cytauxzoonosis is suspected in cats with regenerative anemia and neutrophilic leukocytosis; thrombocytopenia occurs in some cats. Hemoglobinemia, hemoglobinuria, bilirubinemia, and bilirubinuria are uncommon. Antemortem diagnosis is based on demonstration of the erythrocytic phase on thin blood smears stained with Wright's or Giemsa stains. Infected macrophages can be detected cytologically in bone marrow, spleen, liver, or lymph node aspirates. The organism is easily identified on histologic evaluation of most organs. Serologic testing is not commercially available. PCR can be used to amplify organismal DNA from blood.[98]

Supportive care should be administered as indicated. Treatment with diminazene or imidocarb were used in cats that survived infection.[95] Historically, paraquone, buparvaquone, thiacetarsemide therapies have been attempted. However, paraquone and buparvaquone are not routinely available, and thiacetarsemide is toxic for cats and should not be used for the treatment of this parasite. Ticks should be controlled, and cats in endemic areas should be housed during periods of peak tick activity. *Cytauxzoon felis* is not known to be zoonotic.

168.8 FLAGGELATES

168.8.1 Leishmaniasis

Leishmania spp. are flagellates that cause cutaneous, mucocutaneous, and visceral diseases in dogs, humans, and other mammals.[99,100] Rodents and dogs are primary reservoirs of *Leishmania* spp., people and cats are probably incidental hosts, and sandflies are the vectors. Leishmaniasis was considered unimportant in the United States until recently, with cases only reported occasionally.[101–103] In 2000, *Leishmania donovani* infection was confirmed in multiple dogs in a foxhound kennel in New York State.[104] Further investigation documented *L. donovani* or *Leishmania* spp. infection in 30 other foxhound kennels in 20 states and Ontario, Canada, suggesting a competent vector exists in North America. The organism has been transmitted by blood transfusion.[105] A clinically affected cat in Texas was infected by *L. mexicana mexicana*.[102] Flagellated promastigotes develop in the sandfly and are injected into the vertebrate host when the sandfly feeds. Promastigotes are engulfed by macrophages and disseminate through the body. After an incubation period of 1 month to 7 years, amastigotes (nonflagellate) form and cutaneous lesions develop; sandflies are infected during feeding. The intracellular organism induces extreme immune responses; polyclonal gammopathies (and occasionally monoclonal), proliferation of macrophages, histiocytes, and lymphocytes in lymphoreticular organs and immune complex formation resulting in glomerulonephritis and polyarthritis are common.

Dogs generally develop visceral leishmaniasis. Subclinical infection may persist for months or years. Weight loss, normal to increased appetite, polyuria, polydipsia, muscle wasting, depression, vomiting, diarrhea, cough, epistaxis, sneezing, and melena are common presenting complaints. Splenomegaly, lymphadenopathy, facial alopecia, fever, rhinitis, dermatitis, increased lung sounds, icterus, swollen painful joints, uveitis, and conjunctivitis are commonly identified on physical examination.[99,100,106] Cutaneous lesions are characterized

by hyperkeratosis, scaling, thickening, mucocutaneous ulcers, and intradermal nodules on the muzzle, pinnae, ears, and footpads. Cats are usually subclinically infected. One cat had cutaneous nodules on the ear pinna.[102]

Hyperglobulinemia, hypoalbuminemia, proteinuria, increased liver enzyme activities, thrombocytopenia, azotemia, lymphopenia, and leukocytosis with left shift are common. Hyperglobulinemia is usually polyclonal, but an IgG monoclonal gammopathy was reported in a dog.[107] Neutrophilic polyarthritis occurs in some dogs as a manifestation of a Type III hypersensitivity reaction. Antibodies against *Leishmania* can be detected in serum[108–110]; IgG titers develop 14 to 28 days after infection and decline 45 to 80 days after treatment. Because dogs are unlikely to eliminate infection spontaneously, a true positive antibody test indicates infection. Demonstration of amastigotes (2.5 to 5.0 μm × 1.5 to 2.0 μm) in lymph node aspirates, bone marrow aspirates, or skin imprints stained with Wright's or Giemsa stain gives a definitive diagnosis. The organism can also be identified by histopathologic or immunoperoxidase evaluation of skin or organ biopsy, culture, inoculation of hamsters, or PCR. PCR can be performed on EDTA anticoagulated blood, bone marrow, or lymph node aspirates.[109,110]

Leishmania cannot be eliminated from the body with drugs.[108,111,112] The combination of antimony and allopurinol was superior to treatment with either drug alone in one study.[112] Liposomal amphotericin B has also been prescribed.[113] The prognosis is variable; most cases are recurrent. Dogs with renal insufficiency have a poor prognosis.

Avoidance of infected sandflies is the only means of prevention.[114] If in endemic areas, pet owners should house animals during nighttime hours and control breeding places of sandflies. Potential blood donors from endemic areas should be serologically screened.[105] The primary zoonotic risk for canine leishmaniasis is from dogs acting as a reservoir host for the organism. Direct contact with amastigotes in draining lesions is unlikely to result in human infection.

168.9 AMERICAN TRYPANOSOMIASIS

Trypanosoma cruzi infection of mammals is diagnosed primarily in South America, but several cases have been detected in dogs of North America.[115–123] Infected reservoir mammals (dogs, cats, raccoons, opossums, armadillos) and vectors (reduviid bugs, kissing bugs) are found in the United States, but infection in dogs or people is rare; this may relate to differences in vector behavior and sanitation standards in the United States. In one study in Texas, the number of serologically positive dogs increased between 1987 and 1996.[116] The organism has three life stages: (1) trypomastigotes (flagellated stage found free in blood), (2) amastigotes (nonflagellated intracellular form), and (3) epimastigotes (flagellated form found in the vector). When infected kissing bugs defecate during feeding, epimastigotes enter the vertebrate host, are engulfed by macrophages and myocytes, and transform into amastigotes. Amastigotes divide by binary fission until the host cell ruptures, releasing trypomastigotes into circulation. The vector is then infected by ingesting trypomastigotes during a blood meal. Transmission can also occur by ingesting the vector, by blood transfusions, by ingestion of infected tissues or milk, or transplacentally.

Disease in dogs is primarily a cardiomyopathy that develops from parasite-induced damage to myocardial cells or immune-mediated reactions. Exercise intolerance and weakness are nonspecific presenting complaints that relate to myocarditis or heart failure during acute infection. Generalized lymphadenopathy, pale mucous membranes, tachycardia, pulse deficits, hepatomegaly, and abdominal distension can be detected on physical examination. Anorexia, diarrhea, and neurologic signs occasionally occur. Dogs that survive acute infection can present for

644 645

evaluation of chronic dilative cardiomyopathy. In one study of 11 dogs with chronic infection, right-sided cardiac disease, conduction disturbances, ventricular arrhythmias, and supraventricular arrhythmias were most common.[116]

Common clinicopathologic abnormalities include lymphocytosis and increased activities of liver enzymes and creatine kinase. Thoracic radiographic, abdominal radiographic, and echocardiographic findings are consistent with cardiac disease and failure, but they are not specific for trypanosomiasis. The primary ECG findings are ventricular premature contractions, heart block, and T-wave inversion. Definitive diagnosis is based on organism demonstration. Tryptomastigotes (1 flagellum, 15 to 20 µm long) can be identified during acute disease on thick blood film or buffy coat smears stained with Giemsa or Wright's stain. The organism is sometimes detected in lymph node aspirates or in abdominal effusions. Histopathologic evaluation of cardiac tissue may reveal amastigotes (1.5 to 4.0 µm). Tryptomastigotes can also be cultured from blood or grown by bioassay in mice. In North American cases, positive serologic test results correlate with infection. PCR can also be used to detect infection.

Nifurtimox administered at 2 to 7 mg/kg orally every 6 hours for 3 to 5 months has been prescribed most frequently but is not routinely available. Glucocorticoid therapy may improve survival of infected dogs. Therapy for arrhythmias or heart failure should be instituted as needed. Most dogs that survive acute infection will develop dilative cardiomyopathy. Survival time in 11 dogs varied from 0 to 60 months.[116]

Dogs should be kept from other reservoir hosts such as opossums and should not be fed raw meat. Potential blood donors from endemic areas should be serologically screened. Infected dogs can serve as a reservoir of *T. cruzi* for vectors, and blood from infected dogs can be infectious to humans. Vector control is the primary means of prevention.

168.10 AMOEBA

168.10.1 Acanthamoeba Spp.

Acanthamoeba castellanii and *A. culbertsoni* are free-living amoeba rarely associated with disease in dogs.[124–126] Several cases have been reported in greyhounds. Young dogs seem to be affected most often. Clinical signs resemble CDV infection and consist primarily of oculonasal discharge, fever, anorexia, lethargy, dyspnea, and CNS disease. No pathognomic laboratory or radiographic abnormalities exist, but leukopenia is common. The organism can be demonstrated histologically or cultured; antemortem diagnosis is not usually made. No known effective treatment or zoonotic risk exists.

168.11 MICROSPORA

168.11.1 Encephalitozoon Cuniculi

Dogs and cats can develop clinical illness after exposure to *Encephalitozoon cuniculi*.[127–129] Schizonts and sporonts are found intracellularly in many cell types including renal tubular epithelial cells, endothelial cells, tissue macrophages, and hepatocytes. Spores are the extracellular stage of the organism that is passed in urine. Infection is probably from oronasal exposure to spores passed in urine. In utero infection can also occur; infected puppies are weak, have stunted growth, and develop renal failure and CNS disease. Muscle spasms, depression, paralysis, and death have been reported in naturally infected cats. No pathognomonic laboratory abnormalities exist; however, azotemia, increased activities of hepatic enzymes, and increased CSF cell counts

(neutrophils) and protein concentrations commonly occur. Diagnosis is based on demonstration of spores in urine sediment stained with Gram or Ziehl-Neelsen stains. Serologic testing is available but is not specific for *E. cuniculi*. Although no drug has been shown to be effective for treatment of *E. cuniculi* in infected dogs or cats, fumigillin and albendazole were effective in vitro.[130] Although the zoonotic risk is considered minimally important, a 10-year-old girl in a home with two infected puppies seroconverted to *E. cuniculi*.[129] Sanitation is the best form of control.

168.12 MISCELLANEOUS INFECTIOUS AGENTS

168.12.1 Pneumocystosis

Pneumocystis carinii is a saprophytic organism with worldwide distribution that has characteristics of protozoans, yeast, and fungi that has been detected in diseased dogs.[131–136] The organism is found in the alveoli of some normal animals. Disease only occurs in immune-suppressed individuals. Replication of the organism in the alveoli induces infiltrates of lymphocytes, plasma cells, and macrophages that induces an alveolar-capillary blockage. Disseminated infection is rare in dogs and people. Disease has been detected in cats given corticosteroids.[137] Pneumocystosis in animals is extremely rare and only associated with concurrent immune deficiency. Miniature dachshunds with common variable immunodeficiency syndrome are affected most frequently.[131–132]

Most affected dogs have been less than 1 year of age. Predominant findings are dry cough, dyspnea, and progressive weight loss. Dermatopathies such as demodicosis and pyoderma that likely reflect the immune deficiency occur with most.

Neutrophilic leukocytosis, polycythemia, eosinophilia, and monocytosis occur in some dogs but are nonspecific findings. Common blood gas abnormalities include hypoxemia, hypocapnia, and an increased arterial-alveolar gradient. On thoracic radiographs, interstitial to alveolar patterns predominate.[138] Cor pulmonale can develop. Cytologic demonstration of the organism in transthoracic aspirates, transtracheal wash specimens, or lung biopsies is used to make the final diagnosis. Immune function deficits have been documented in affected dachshunds. Diffuse interstitial pneumonia characterized by free and phagocytosed organism in the alveolar spaces is found on histopathologic examination.

Administration of potentiated sulfas give the best results.[131,132] Pentamidine, carbutamide, trimetrexate, the combination of clindamycin and primaquine, and the combination of dapsone and trimethoprim have been used to treat pneumocytosis in some dogs. Supportive care, including oxygen therapy, bronchodilators, nebulization, and mucolytic agents, should be administered as indicated. For most cases, death occurs or euthanasia is chosen within days to months after diagnosis. Infected dogs are not considered zoonotic risks for people.

168.13 PROTOTHECOSIS

Prototheca zopfii and *P. wickerhamii* are the two species in this genus of green algae incriminated as pathogens; protothecosis is a disseminated disease in the dog *(P. zopfii)* and a cutaneous disease in the dog and cat *(P. wickerhamii)*.[139–142] The organism is found in sewage and animal wastes and is transmitted by ingestion of contaminated food, water, or soil. Disease generally only occurs in individuals with decreased cell-mediated immune responses. There may be strain differences in virulence and genetic predispositions.

The disseminated disease is most common in dogs that present for evaluation of weight loss, large-bowel diarrhea, CNS disease, or uveitis. The cutaneous disease occurs in dogs and cats and appears as draining ulcers and crusts of the trunk, extremities, and mucous membranes in dogs and as firm cutaneous nodules on the limbs, feet, and head of cats. CSF abnormalities include pleocytosis with either lymphocytes or granulocytes as the predominate cell type and increased total protein. Diagnosis is confirmed by cytologic, histologic, or culture documentation of the organism in CSF, rectal scrapings, or rectal biopsies. Cutaneous lesions should be excised if possible. Liposomal amphotericin B, ketoconazole, itraconazole, tetracyclines, and fluconazole may be effective treatments. CNS and ocular manifestations have a poor prognosis; fluconazole may be the drug of choice for disease of these systems. Topical clotrimazole may be effective for treatment of cutaneous *P. wickerhamii* infections. *Prototheca* spp. are not thought to be transmitted between hosts; therefore zoonotic risk is minimal.

169 CHAPTER • 169 Canine Viral Diseases

Rance K. Sellon

169.1 CANINE PARVOVIRUS

169.1.1 Cause and Epidemiology

Parvovirus of dogs is caused by type 2 canine parvovirus (CPV-2), a nonenveloped single-stranded DNA virus, of which two pathogenic variants, types 2a and 2b are recognized. Evidence suggests an evolution of the type 2a variant to the type 2b, with the 2b variant the most common isolate infecting dogs in the United States. Both variants can be found in other parts of the world. A third variant, type 2c, has recently been found in cats in Southeast Asia.[1]

Wild and domestic canids are susceptible to infection with CPV-2. Canine parvovirus (CPV) infection has been described in minks and ferrets, and all variants are known to infect cats. The virus is transmitted primarily by the fecal-oral route after exposure of susceptible animals to contaminated feces. CPV is quite stable under many environmental and hospital conditions, contributing to maintenance of the virus in natural settings and creating the potential for transmission in veterinary clinics. CPV is resistant to many detergents and disinfectants, although it is inactivated by bleach solutions (1 part bleach to 29 parts water), formalin, and sunlight.

169.1.2 Pathogenesis

After exposure, CPV replicates in lymphoid cells in the oropharynx, mesenteric lymph nodes, and thymus, then within 3 to 5 days it spreads hematogenously to crypt cells of the small intestine and epithelial cells of the oral cavity, tongue, and esophagus. Lymphoid organs, lungs, liver, kidneys, bone marrow and (in very young animals) myocardial cells may also become infected. Virus excretion begins shortly after infection of intestinal epithelial cells and can occur as soon as 3 to 4 days after exposure; virus excretion typically occurs for 1 to 2 weeks. In the intestinal tract, necrosis of infected crypt cells leads to villus collapse and loss of intestinal epithelial integrity. The hemorrhagic diarrhea that is characteristic of the clinical disease results from a combination of increased intestinal permeability and malassimilation from abnormal mucosal function. Breakdowns in the intestinal epithelial barrier predispose to translocation of intestinal bacteria and absorption of bacterial endotoxins into the systemic circulation (common events in parvoviral-infected dogs).[2,3] Translocation of bacteria and endotoxins can lead to systemic bacteremia and the systemic inflammatory response syndrome, disseminated intravascular coagulation (DIC), and death. Activation of systemic immune responses increases the risk of thromboembolic complications of CPV infection.[4]

169.1.3 Clinical Signs

Clinical features in infected dogs range from asymptomatic infection to fulminant disease and rapid death. The majority of dogs will not develop obvious clinical signs, but in very young animals, immune-suppressed, heavily parasitized or stressed animals, or animals at risk of disease because of breed-related susceptibility, clinical signs often start with anorexia, lethargy, and fever that progresses within 1 to 2 days to vomiting and diarrhea, which is often hemorrhagic. More severe gastrointestinal (GI) signs can be expected in puppies with intestinal parasites or other intestinal disease.

Uncommonly, clinical signs of myocarditis may be observed in very young puppies, typically those less than 8 weeks of age that have not benefited from receipt of maternal antibodies. Puppies may die acutely with no warning, or they may die after signs of enteric disease. Puppies that survive acute myocardial infection may succumb at later times to congestive heart failure (CHF).

169.1.4 Diagnosis

The development of characteristic clinical signs in a dog at risk of infection often provides the first suspicion of CPV. Assays based on enzyme-linked immunosorbent assay (ELISA) techniques to detect CPV antigen in stool samples are commonly used for suspect animals as a first-line diagnostic tool and represent a quick, relatively accurate, and inexpensive means of supporting the diagnosis. Limitations of fecal ELISA testing include brief periods of antigen shedding, varying levels of antigen shedding, and the inability of current tests to discriminate modified-live viral (MLV) vaccine isolates, which can be present in feces for around 1 week starting about 5 days after vaccination, from pathogenic isolates. Thus false negatives and false positives are possible. The development of polymerase chain reaction (PCR)-based assays may prove valuable in the future for discrimination of vaccine from field isolates.

Laboratory abnormalities are common in dogs with clinical CPV infection. Leukopenia and neutropenia can reflect either marrow infection or sepsis and generally parallel the severity of clinical infection; recovery of circulating neutrophil counts often precedes clinical improvement. Anemia and hypoproteinemia, which can be a consequence of hypoalbuminemia, hypoglobulinemia, or both can develop from enteric blood loss. Vomiting and diarrhea can contribute to electrolyte abnormalities and dehydration leading to prerenal azotemia.

Intestinal intussusceptions are a recognized complication of CPV infection.[5] Puppies with refractory vomiting and diarrhea may need abdominal radiographs to rule out such obstructions.

169.1.5 Treatment

No treatment directed at the virus itself exists, so therapy revolves around supporting effective circulating volume, controlling secondary bacterial infections, and resting the GI tract.[6] Administration of replacement type crystalloid fluids such as lactated Ringer's or 0.9% saline at volumes sufficient to restore and maintain hydration in the face of ongoing fluid losses is a key element of therapy. Supplementation of fluids with potassium and dextrose may be needed to maintain normal serum potassium and glucose concentrations in ill puppies. Administration of crystalloid fluids may contribute to the development of anemia and hypoproteinemia as a consequence of rehydration in conjunction with previous and ongoing enteric blood loss. Puppies that become severely anemic are candidates for blood transfusions, with whole blood preferred for animals that are both anemic and hypoproteinemic. Colloid administration may be indicated in puppies that are hypoproteinemic but not anemic enough to require erythrocyte support.

Puppies with vomiting and diarrhea are typically maintained NPO (nothing by mouth) until such signs have resolved; partial parenteral nutrition may be considered for nutritional support of these animals.[6] Parenteral administration of broad-spectrum antimicrobials with good gram-negative spectra is considered a key aspect of treatment. Good combinations include an aminoglycoside or fluoroquinolone with a beta lactam in the penicillin (amoxicillin, ampicillin) or first-generation cephalosporin families. Fluaroquinolones may cause cartilage abnormalities if administered to puppies.

Other considerations in the supportive care of affected dogs include control of persistent vomiting with antiemetic drugs such as metoclopramide, phenothiazine derivatives (e.g., chlorpromazine), or serotonin antagonists (e.g., ondansetron), although the latter category of drugs is comparatively expensive. Administration of hyperimmune or antiendotoxin serum has also been advocated.[6] Use of recombinant human granulocyte colony–stimulating factor (rHuG-CSF) has been suggested as an adjunctive treatment of neutropenic dogs to improve neutrophil counts. However, one study of a small number of dogs suggested no clinical benefits in recipients of rHuG-CSF as compared with a control group, and an additional study found that peak endogenous granulocyte colony–stimulating factor (G-CSF) concentrations in CPV-infected dogs occurred at the peak of neutropenia, raising the question as to whether higher concentrations of G-CSF would be of any additional benefit.[7,8] Given the expense of rHuG-CSF, its use is not easily justified. Glucocorticoids and nonsteroidal anti-inflammatory drugs (NSAIDS) may be considered for use in puppies suspected of endotoxemia or sepsis, although their benefits need to be carefully weighed against their potential risks.

Once vomiting has stopped, patients may be offered water. If no more vomiting occurs, food may then be offered. Diets in the initial feeding period should be easily digestible, low-fat foods because villus structure and function may require a number of days to return to normal. A number of diets are commercially available for the benefit of patients recovering from gastroenteritis. Administration of anthelmintics is appropriate at this time as well.

Given adequate supportive care, many affected puppies survive infection. Once recovered, puppies are considered immune to reinfection for long periods—possibly for life.

169.1.6 Prevention

The cornerstone of prevention of CPV infection is vaccination. CPV vaccines are available in live or killed forms, with the latter sometimes used in breeds considered at greater risk of clinical CPV infection, in pregnant animals in need of vaccination, or animals with diminished immune function. Live-virus vaccines produce an asymptomatic infection with a longer duration of immunity than is considered achievable with inactivated vaccines. The use of low-passage (increased antigenicity), high-titer (larger viral inoculum) vaccines incorporating highly immunogenic CPV-2 strains is advised for most dogs to provoke a protective immune response in the presence of maternal antibodies. Recommended schedules are to begin vaccinations at 6 weeks of age with boosters at 9 and 12 weeks of age. For breeds such as Doberman pinschers, Rottweilers, or others that are considered to be at greater risk of infection, an additional booster vaccination around 15 to 16 weeks of age or measurement of serum neutralization or hemagglutination inhibition (HI) antibody concentrations has been recommended. All dogs should receive a booster vaccine 1 year after completion of the initial series. The frequency of vaccination recommended in adult dogs is a subject of some controversy, and support for extending vaccine intervals beyond 1 year exists.[9] Recent recommendations from a canine vaccine advisory board are for adult dogs to receive boosters to CPV every 3 years.[10] The interval chosen should reflect assessment of the risks and benefits of vaccination for each patient. Measurement of serum neutralization or HI titers may be considered as a guide to dictate the need for vaccination because, in general, higher serum titers tend to correlate with protection from infection.

169.2 CANINE CORONAVIRUS

169.2.1 Cause and Epidemiology

Canine coronavirus (CCV) is an enveloped single-stranded RNA virus in the family Coronaviridae. CCV can infect many species of canids. The virus is relatively stable in the environment but can be disinfected by many compounds. The virus is spread primarily by the fecal-oral route to susceptible dogs.

169.2.2 Pathophysiology

CCV infects epithelial cells in the villus tips of the small intestine. A malabsorptive diarrhea results as a consequence of loss of villus surface area. After infection, CCV is shed in the feces for 6 to 9 days, but the duration of shedding can be longer in some animals. The development of a local intestinal immune response terminates clinical signs and ultimately viral shedding.

169.2.3 Clinical Signs

Diarrhea is the principle clinical sign in clinically affected dogs; blood in the feces is an infrequent finding. Vomiting may be seen before or after diarrhea in some animals. Anorexia and lethargy are common features, and if vomiting and diarrhea are severe, dehydration may ensue. Clinical disease from CCV is considered infrequent compared with other viral enteropathies and is usually more severe in neonatal animals, with diminishing severity of clinical disease in older animals. Clinical signs abate after 7 to 10 days in most dogs, but the clinical course may be longer in dogs that develop secondary complications or infection.

169.2.4 Diagnosis

The definitive diagnosis of CCV historically has required the demonstration of virus in the stool, usually by electron microscopy. PCR-based techniques, although not yet commercially available, have been developed as a means to detect viral nucleic acid in the stool.[11]

647

648

169.2.5 Treatment

Treatment of CCV is primarily supportive during the time needed for the disease to run its natural course. Dehydrated animals may require parenteral fluids. The role of antibiotics in the treatment of CCV has not been assessed. The use of antibiotics in dogs with diarrhea, though not universally accepted, has been supported because bacteria may be primary or secondary pathogens and attempts to define viral causes may not always be made.[12]

169.2.6 Prevention

CCV vaccines are available, but efficacy of protection is questioned.[10] CCV vaccines are not considered core vaccines, but tend to be reserved for animals going into situations where the risk of exposure may be higher (kennels, shows).

169.3 CANINE ROTAVIRUS

169.3.1 Cause and Epidemiology

Canine rotavirus enteritis is most often caused by a group A rotavirus in the family Reoviridae, which are nonenveloped double-stranded RNA viruses. Recently, group C rotaviruses, which are more commonly found in other species such as pigs, have been documented in diarrheic dogs.[13] Infection usually occurs via the fecal-oral route, and causes subclinical or mild gastroenteritis in young animals, especially puppies less than 14 days of age. A high seroprevalence is found in adult dogs. Compared with other enteric viruses, clinical disease caused by rotavirus appears to be uncommon.[12,14]

169.3.2 Pathogenesis

After exposure, rotavirus infects epithelial cells of the villus tip of the jejunum and ileum. Loss of villus epithelial cells ensues with development of villus atrophy. Virus is shed early as infected, necrotic epithelial cells are sloughed from the villus.

169.3.3 Clinical Signs

Anorexia, vomiting, and mild diarrhea, which can occasionally be bloody, are the typical clinical signs of rotaviral gastroenteritis. Recovery is expected in most animals within 5 to 7 days of onset of clinical signs.

169.3.4 Diagnosis

A variety of tests to detect rotaviral antigens are commercially available but are not commonly used in small animal practice. Other methods to obtain a definitive diagnosis include demonstration of virus in stool samples by electron microscopy or PCR.

169.3.5 Treatment

Therapy of rotavirus gastroenteritis is supportive care, with attention to maintenance of hydration status the key element in puppies with anorexia and vomiting.

169.3.6 Prevention

No vaccine is currently available for prevention of rotaviral infection.

169.4 CANINE ADENOVIRUS

169.4.1 Cause and Epidemiology

Canine adenovirus type 1 (CAV-1), a nonenveloped double-stranded DNA virus in the Adenoviridae family, is the cause of infectious canine hepatitis (ICH) and causes disease in domestic and wild canids and bears. The

virus is relatively hardy, surviving in the environment for days to months, and is resistant to most disinfectants except quaternary ammonium compounds. Infection occurs after oronasal exposure to infectious secretions.

169.4.2 Pathogenesis

After exposure, CAV-1 replicates in lymphoid tissue of the tonsils and area lymph nodes. A viremia follows, leading to infection of other tissues. Direct cytopathic effects of the virus in the liver, eyes, and kidney contribute to early clinical signs, which can become apparent in naïve dogs 4 to 7 days after exposure. The extent of hepatic necrosis is a function of the level of antiviral antibody present at the time of infection: animals with minimal antibody exhibit extensive necrosis that is often fatal; dogs with high levels of antibody exhibit minimal clinical signs; and animals with intermediate antibody levels are susceptible to persistent hepatic inflammation. Clinical signs of anterior uveitis initially develop as a consequence of infection of corneal endothelial cells, then by inflammation provoked by deposition of immune complexes as antibody responses to the virus increase. Virus is shed during the acute infection in all body secretions including saliva, stool, and urine; excretion of virus in urine can persist for months after infection, but urinary virus is not thought to contribute greatly to transmission.

169.4.3 Clinical Signs

Initial clinical signs include fever, depression, and lethargy, with later development of abdominal discomfort, mucous membrane pallor, and inflammation of the tonsils and pharynx with tonsillar and cervical lymph node enlargement. Abdominal discomfort and hepatomegaly will be detected in some dogs, and coughing may be seen in cases of respiratory disease. Vomiting and diarrhea can also occur. In severe cases, petechial and ecchymotic hemorrhages may develop from coagulation abnormalities secondary to hepatic dysfunction and DIC. Icterus is uncommon despite the presence of hepatic necrosis. Neurologic signs may be seen as a consequence of hepatic encephalopathy or central nervous system (CNS) infection; measurement of bile acids or plasma ammonia concentrations, if elevated, would support a contribution of hepatic encephalopathy to observed neurologic signs. Dogs with severe disease may die within hours after showing clinical signs, whereas dogs with less severe disease may exhibit clinical improvement 5 to 7 days after onset of clinical signs.

169.4.4 Diagnosis

The diagnosis of CAV infection is usually based on finding evidence of acute hepatic disease in a dog with a poor vaccination history. No specific laboratory abnormalities pathognomonic for CAV infection are seen. There may be leukopenia or leukocytosis depending on whether the patient is seen early or later in the course of disease. Thrombocytopenia is possible and could contribute to coagulopathies in the setting of DIC or abnormal platelet function. Increases in alanine aminotransferase (ALT) and alkaline phosphate (ALP) activity are expected, but the magnitude of activity will depend on the extent of hepatic necrosis and the timing of sample collection. Prolongations of OSPT and APTT are common as a result of decreased hepatic synthesis of coagulation factors, DIC, or both. Proteinuria is also expected as a sequel to renal injury during viremia or immune complex injury later in the course of disease.

Definitive diagnosis of CAV infection can be established if needed through serological, viral isolation, or immunohistochemical techniques. Inclusion bodies observed during cytologic or histologic examination of tissue, particularly the liver, can be strongly supportive of the diagnosis.

169.4.5 Therapy

No specific treatments exist that address the virus, and therapy is directed at provision of supportive care and managing clinical signs and complications. Intravenous fluid therapy to replace losses from vomiting or diarrhea is important, as is administration of blood products (whole blood, fresh or fresh frozen plasma) to manage the complications of hemorrhage and DIC. In patients with neurologic signs from hepatic encephalopathy, administration of lactulose via enema (or orally if the patient is not vomiting and can tolerate oral medications) can help reduce circulating concentrations of encephalotoxins.

648 649

169.4.6 Prevention

As with other important canine viral diseases, vaccination is the foundation of prevention of CAV-1 infection. Most commonly used vaccines to CAV-1 use CAV-2 isolates which, through the production of cross-reactive antibodies, will elicit a protective immune response without the complications, such as corneal edema, seen more often after vaccination with vaccines using CAV-1 isolates. The duration of immunity after immunization with CAV-2 MLV vaccines is likely long, and revaccination every 3 years after a routine initial series and booster at 1 year of age has been recommended.[10]

169.5 CANINE DISTEMPER VIRUS

169.5.1 Cause and Epidemiology

Canine distemper virus (CDV) is caused by an enveloped single-stranded RNA *Morbillivirus* in the Paramyxoviridae family and is closely related to viruses that cause measles, rinderpest, and distemper in other animals. CDV is capable of infecting a large variety of species including dogs, mustelids (e.g., ferrets, skunks), and procyonids (e.g., raccoons). The virus does not survive for long periods outside of the host and is susceptible to inactivation with a number of disinfectants such as phenolic or quaternary ammonium compounds. CDV is most often spread by inhalation of virus particles in respiratory aerosols or aerosols of other infected secretions such as urine.

169.5.2 Pathogenesis

After exposure, virus infects and replicates in macrophages, which spread virus to regional lymph nodes and tonsils, with virus reaching a peak in these tissues by 2 to 4 days after inoculation. By around 4 to 6 days postinfection (PI), virus has spread to, and is multiplying in, the stomach, small intestine, spleen, and hepatic macrophages. The widespread increase in virus production is associated with initial fever and lymphopenia.

After about 9 to 14 days PI, the outcome of infection is dictated by the strength and type of the host's immune response. Dogs with poor immune responses develop viral infection of several additional tissues including skin, CNS, and glandular and epithelial organs. Such animals generally exhibit severe clinical signs and are likely to die as a result of infection. Those animals that recover from the initial clinical signs maintain virus in tissues and are likely to subsequently develop clinical signs of CNS disease.

In animals that mount an intermediate level of immune response, mild or clinically silent infection may develop, with virus persisting in the lungs, skin, or CNS. Such animals may undergo a complete recovery or

may develop signs of CNS disease. Animals that mount strong immune responses are unlikely to develop signs of systemic infection but may still develop signs of CNS disease.

The pathogenesis of neurologic disease in CDV-infected dogs is complex. Dogs, especially those that are very young or immune-suppressed, may develop acute encephalitis, which is attributed to direct viral injury. Chronic encephalitis appears to be a consequence of inflammatory responses to viral antigens in CNS cells, with macrophage activation and release of cytotoxic mediators playing a role in destruction and demyelinization of CNS cells.

169.5.3 Clinical Signs

The severity of the clinical course is a function of the age of the animal at the time of infection, the viral strain, and immune responses. Affected dogs may be lethargic, anorexic, and febrile. Animals with respiratory infection may exhibit serous or mucopurulent oculonasal discharge and cough. More severely affected animals can show an initial conjunctivitis followed by cough, vomiting, and diarrhea that can be bloody or mucoid.

Neurologic signs may develop starting 1 to 3 weeks after recovery from systemic signs or can develop many more weeks to months later. Curiously, certain features of clinical disease tend to correlate with the likelihood of developing neurologic disease. Dogs that develop pustular skin lesions are less likely to develop CNS disease than dogs that exhibit hyperkeratosis of the nasal planum and digital footpads, which is frequently associated with the development of neurologic signs. Neurologic abnormalities can reflect lesions in any CNS site and include seizures, ataxia, hypermetria, and paraparesis or tetraparesis. Myoclonus, either generalized or focal, is a common clinical sign and is strongly suggestive of CDV infection.

Other clinical signs that can be seen include anterior uveitis and chorioretinitis; recovered animals may have hyper-reflective retinal lesions that develop from retinal atrophy and scarring. Optic neuritis may cause blindness or mydriasis; blindness can also result from serous retinal detachments. Some dogs, especially young large breed dogs, are susceptible to metaphyseal osteosclerosis of long bones, which is typically not associated with lameness. Puppies infected in utero or as neonates can develop CNS signs early in life, or have enamel hypoplasia if infected before the eruption of permanent teeth. Abortions or neonatal death may also be appreciated.

169.5.4 Diagnosis

Diagnosis of CDV is usually a clinical one, relying on compatible clinical signs in a young animal with a poor vaccination history. However, CDV should not be excluded as a differential in a dog with compatible clinical signs if the animal has a vaccination history.[15] No pathognomonic laboratory abnormalities are seen. Lymphopenia is the most consistent CBC abnormality. There may be CDV inclusions in monocytes, lymphocytes, neutrophils, or erythrocytes seen during examination of a stained blood smear. Biochemical profile abnormalities can include hypoalbuminemia and hypoglobulinemia. The CSF may have (1) increased numbers of lymphocytes and monocytes and increased protein, (2) increased protein only, or (3) may be normal.[15]

Dogs with respiratory disease may have interstitial or alveolar patterns on thoracic radiographs. Radiographs of long bones in lame animals may have metaphyseal lesions consistent with hypertrophic osteodystrophy.

Animals with CDV neurologic disease can be diagnostic challenges if no history of systemic signs exist. Definitive diagnosis of CDV can be made by demonstration of higher concentration of CDV antibody in the

CNS as compared with the serum, although not all animals will have CSF antibodies.[15] Demonstration of viral antigen in cells or tissues by immunohistochemical methods such as fluorescent antibody (FA) testing of conjunctival swabs or blood smears also confirms the diagnosis. Recently, reverse-transcriptase polymerase chain reaction (RT-PCR) assays have proven sensitive and specific for detection of CDV in experimental settings and can be performed on virtually any tissue type.[16] Such assays performed on whole blood, serum, or CSF may be more sensitive for detection of CDV than antigen or antibody demonstration techniques. The RT-PCR is not commercially available but holds future promise as a diagnostic tool.

649

650

169.5.5 Treatment

Treatment of dogs with CDV is largely supportive. Parenteral administration of fluids may be needed in dogs with vomiting or severe diarrhea. Animals with secondary bacterial bronchopneumonia or other infections are candidates for antibiotics. Seizure control with diazepam, pentobarbital, or potassium bromide may be needed. The prognosis for dogs with neurologic disease is considered guarded to poor.

169.5.6 Prevention

The key to CDV prevention is vaccination. Current MLV or recombinant vaccines are effective at inducing immunity. Distemper-measles vaccines may be given to high-risk puppies 4 to 12 weeks of age to provide protection in the face of maternal CDV antibodies. The duration of immunity after immunization with MLV CDV products is considered long lasting, and vaccination intervals of 3 years have been supported.[10]

Immunization of dogs with MLV CDV vaccine has been associated with postvaccinal complications, the most common of which is encephalitis, which can produce clinical signs of neurologic disease and variable neurologic abnormalities 7 to 14 days after vaccination. Though not widely available, molecular techniques such as restriction fragment length polymorphism analysis may help distinguish clinical disease caused by vaccine isolates from that caused by field isolates.[17]

169.6 RABIES VIRUS

169.6.1 Cause and Epidemiology

Rabies virus is an enveloped single-stranded RNA virus in the family Rhabdoviridae. Rabies virus is capable of infecting all mammals, although differences exist in susceptibility to infection. Skunks, wild dogs, bats, raccoons, and cattle are most susceptible, whereas domestic dogs, cats, horses, sheep, and goats are considered to have moderate susceptibility. In the United States the principle reservoirs of rabies virus for domestic dogs are skunks, raccoons, and foxes.[18] The virus is not stable in the environment and is inactivated by most common disinfectants. Rabies virus is spread primarily by inoculation of a naïve animal with infected saliva, thus bite wounds are the most common mode of rabies virus transmission. Transmission by ingestion of infected tissue, inhalation of airborne virus, and transplacental transmission have been described but are considered rare.

169.6.2 Pathogenesis

After inoculation, virus replicates in local tissue then enters nerve endings through neuromuscular junctions or breaches in the axonal sheath of injured nerve fibers. Virus spreads along axons in the peripheral nerves to the

CNS. Once the CNS has been entered, virus spreads among adjacent axons to involve more neurons and spreads more rapidly to the brain stem and then forebrain. The virus replicates in the CNS and moves out of the CNS to other tissues along peripheral nerve fibers. Infection of salivary glands occurs during this time, and thus virus in the saliva is a reflection of CNS infection. Virus can be shed in the saliva up to almost 2 weeks before neurologic signs develop. In rare instances documented in experimentally infected dogs, virus excretion may persist for several months after resolution of neurologic signs.

169.6.3 Clinical Signs

Rabies can be variable in its clinical presentation, and suspicion can be delayed because of atypical signs. Clinical suspicion may be further delayed because of variable incubation periods after inoculation of virus; incubation periods reflect the size of the viral inoculum, the extent of nerve supply to injured tissue, the distance from the site of inoculation to the spinal cord, and host factors such as age and immune responses. Clinical signs often start with a prodromal phase of 2 to 3 days that is characterized by nervousness, anxiety, or other behavior changes. There may be paresthesia at the site of inoculation. As clinical signs progress, forebrain signs of irritability, restlessness, pica, as well as photophobia and hyperesthesia may be apparent. These clinical signs, often referred to as the *furious form of rabies*, can progress to incoordination, seizures, and death. Paralytic or dumb forms of rabies are characterized by lower motor neuron disease beginning in the area of initial injury and eventually involving the entire CNS. Dysphagia from paralysis of the muscles of deglutition causes accumulation of saliva in the oral cavity, which can be a source of infection to owners and veterinarians attending to such patients. Death follows as the animal develops coma and respiratory paralysis.

169.6.4 Diagnosis

Rabies should be suspected in any animal with an uncertain vaccination history exhibiting neurologic or behavioral abnormalities. Definitive diagnosis hinges on demonstration of virus in the brain, with direct FA testing considered the preferred method in many laboratories. Heads or bodies of suspect animals should be submitted to appropriate diagnostic laboratories without freezing to avoid damage to brain tissue associated with thawing. Detection of intracellular inclusions (Negri bodies) or direct FA testing of sensory vibrissae in the maxillary area is considered insensitive as compared with direct FA of nervous tissue. The application of molecular techniques such as the PCR may be of benefit in situations where brain tissue is not available or is not suitable for FA testing and offers potential advantages in detecting low levels of virus or virus in saliva.

169.6.5 Treatment

Treatment of animals suspected of having rabies is not recommended because of the human health hazard posed by such animals. Asymptomatic animals that are considered suspects should be isolated according to local laws and regulations or euthanized for collection and submission of brain tissue to diagnostic laboratories.

169.6.6 Prevention

Vaccination is an effective measure in the prevention of rabies in dogs and cats. Most commonly used vaccines contain inactivated virus given initially to animals older than 3 months of age with a booster at 1 year of age. The need for subsequent boosters either annually or every 3 years is predicated upon the product used and local laws regarding rabies prophylaxis. Recent epidemiologic studies have suggested that unvaccinated, owned animals represent the largest population of rabid dogs and cats.[18] Such findings emphasize the importance of client education, especially in areas in which rabies is endemic.

169.7 PSEUDORABIES

169.7.1 Cause and Epidemiology

Pseudorabies is caused by an enveloped double-stranded DNA virus in the alpha-herpesvirus family. Despite the presence of an envelope, pseudorabies virus is relatively stable in the environment. Affected dogs usually have a history of having been in contact with pigs, which are the main reservoirs of the virus. Most cases in dogs are believed to result from the ingestion of infected raw pork.

169.7.2 Pathogenesis

After ingestion, the virus enters nerve endings in the mucosa and spreads to the brain along nerve axons. Inflammation and functional abnormalities in brain cells result in neurologic signs after an incubation period of around 3 to 6 days.

650

651

169.7.3 Clinical Signs

Signs of neurologic dysfunction are common features of the disease.[19] Neurologic abnormalities can be variable and have included ataxia, abnormal pupillary light responses, restlessness, trismus, and cervical rigidity. Ptyalism, tachypnea, and hyperpnea are common. Pruritus of the head and neck area can lead to self-induced excoriation. In some dogs, vomiting and diarrhea are the predominant signs. The clinical course of pseudorabies infection in dogs is usually swift, with most dogs dying within 48 hours after onset of clinical signs of acute neurologic disease.

169.7.4 Diagnosis

The diagnosis is suspected based on history of exposure to pigs or pork products and on clinical signs. Definitive diagnosis can be established by demonstration of virus by FA or PCR in the brain and tonsil.

169.7.5 Treatment

Treatment is supportive, although the fulminant nature of the clinical disease and poor prognosis have not seen many animals survive the infection.

169.7.6 Prevention

No approved pseudorabies vaccine exists for dogs, so prevention relies on limiting exposure of dogs to pigs or preventing ingestion of contaminated raw pork products.

169.8 CANINE PARAINFLUENZA VIRUS AND ADENOVIRUS-2

169.8.1 Cause and Epidemiology

Canine parainfluenza virus is a single-stranded RNA virus in the Paramyxoviridae family, and canine adenovirus-2 (CAV-2) is in the family Adenoviridae. The viruses are transmitted primarily from inhalation of aerosolized droplets from infected dogs and are part of a complex of pathogens causing infectious tracheobronchitis in dogs. Dense populations such as in kennels or shelters facilitate viral spread to naïve dogs.

169.8.2 Pathogenesis

Clinical signs develop after an incubation period of 3 to 10 days, during which time virus is replicating in epithelial cells of the upper respiratory tract of infected dogs, causing epithelial destruction. Damage to the epithelial barrier and disruption of normal respiratory defenses afforded by an intact epithelium predispose to infection with other respiratory tract pathogens such as mycoplasma or various bacteria. Viral shedding can occur for approximately 1 week after infection.

169.8.3 Clinical Signs

A hacking cough with a terminal retch and serous nasal discharge are the typical clinical signs of viral infection. Coughing bouts are often easily elicited with tracheal palpation or manipulation, and can be paroxysmal in nature. Coughing may produce foamy white mucus. Clinical signs are typically of short duration and often subside by 7 days after onset, although occasional dogs may exhibit clinical signs for up to 9 to 10 days.

169.8.4 Diagnosis

The diagnosis is typically established by the presence of clinical signs in an otherwise healthy animal with a history of risk factors for infection. No pathognomonic laboratory abnormalities are seen in affected dogs; thoracic radiographs should be normal unless severe infection creates a secondary bronchopneumonia from other respiratory pathogens or the animal has pre-existing respiratory disease. Isolation of virus from nasopharyngeal or tracheal swabs can establish a definitive diagnosis but is rarely performed in clinical practice.

169.8.5 Treatment

No specific treatment is effective for reducing viral loads, so treatment is largely supportive. Administration of antimicrobials such as amoxicillin, ampicillin, or trimethoprim-sulfa may limit the development of secondary bacterial infections that can prolong the clinical course. Antimicrobials are frequently used empirically because of the clinical difficulty in distinguishing clinical signs of viral infection from clinical signs caused by other upper respiratory pathogens such as *Bordetella bronchiseptica*. Judicious short-term use of anti-inflammatory doses of glucocorticoids or administration of cough suppressants, such as hydrocodone or butorphanol tartrate, may help ameliorate cough and improve patient comfort but are unlikely to shorten the clinical course.

169.8.6 Prevention

Vaccination is the mainstay of prevention of viral respiratory infection. Greater protection is afforded animals that receive MLV parainfluenza vaccines intranasally as compared with parenterally administered vaccines. CAV-2 vaccines are usually part of core vaccine programs because they provide cross protection to CAV-1.

169.9 CANINE HERPESVIRUS

169.9.1 Cause and Epidemiology

Canine herpesvirus (CH) is an enveloped, double-stranded DNA virus that infects domestic or wild canids. The virus is transmitted primarily during birth as a puppy passes through the birth canal, contacting infectious secretions of an infected bitch; transmission may also occur transplacentally, and via oronasal secretions from the infected mother. The virus is susceptible to inactivation with most common disinfectants and is not stable at usual environmental temperatures.

169.9.2 Pathogenesis

After oronasal exposure of neonatal puppies, CH first replicates in the epithelial cells of the oropharnyx and in the mucosa of the tonsils. Virus subsequently enters macrophages, which spread virus hematogenously to other tissues including the lymph nodes, spleen, adrenal glands, kidneys, lungs, liver, and CNS. The lower body temperature of neonates, in conjunction with a limited capacity to mount a febrile response, facilitates systemic spread of the virus, which replicates well at lower body temperatures but poorly at higher temperatures.

In older animals, infection tends to be confined to the respiratory and genital tracts, and signs of systemic infection do not develop. Viral DNA persists in neurons of the trigeminal ganglia and lymphocytes in the retropharyngeal lymph nodes.[20]

169.9.3 Clinical Signs

Abortions, or litters of stillborn puppies, may be seen after transplacental infections. Puppies less than 2 to 3 weeks of age are most likely to develop clinical disease. After an incubation period of 3 to 6 days, infected puppies become ill with signs of persistent crying, hypothermia, soft stool, and petechial hemorrhages in mucous membranes. Petechial hemorrhages in abdominal organs and lungs are also typical lesions observed on necropsy of infected puppies. Nursing stops and death usually follows 24 to 72 hours after the onset of clinical signs. Older puppies develop mild signs of respiratory disease with spontaneous recovery and latent infections that may emerge later as a cause of neurologic disease, with signs of ataxia, blindness, or central vestibular disease most common. Infection in adult dogs is usually associated with vaginal or preputial hyperemia, hyperplasia of vaginal mucosal lymphoid follicles, and sometimes submucosal hemorrhages.

651 652

169.9.4 Diagnosis

Diagnosis is made by observation of clinical signs in puppies of susceptible age in conjunction with necropsy lesions. Viral inclusion bodies may be observed in cells surrounding areas of necrosis and hemorrhage. Definitive diagnosis of CH infection centers on demonstration of virus, viral antigen, or nucleic acids by electron microscopy, immunohistochemical techniques, or PCR of tissues or cell cultures inoculated with

infected tissue. Serologic testing for neutralizing antibodies confirms exposure but does not necessarily indicate active infection.

169.9.5 Treatment

Treatment is supportive but often ineffective at preventing neonatal losses. Injection of immune sera pooled from bitches that have had recent losses of litters may help reduce mortality during outbreaks. Keeping puppies warm and hydrated may lessen mortality in affected litters, primarily by limiting the spread of infection amongst uninvolved puppies.

169.9.6 Prevention

Currently no vaccine is available for CH. Spread of infection may be limited by not breeding infected dogs, although discrimination of infected versus exposed dogs is not easily achieved. Females that have previously lost litters to CH infection may raise healthy litters; thus caesarian sections or artificial insemination are not considered useful approaches to limit the spread of infection.

169.10 CANINE ORAL PAPILLOMA VIRUS

169.10.1 Cause and Epidemiology

Canine oral papillomavirus (COPV) is a nonenveloped double-stranded DNA virus in the family Papillomaviridae and is related to papillomaviruses affecting other species, including people. The virus is relatively stable in the environment.

169.10.2 Pathogenesis

The virus primarily infects cells in the basal layer of the epithelium of the oral cavity, penis, vulva, conjunctiva, and skin, and it is likely that different papillomaviruses account for differences in lesion distribution.[21] Once infected, basal cells increase mitotic activity to produce the characteristic warts.

169.10.3 Clinical Signs

The primary clinical sign of COPV infection is the appearance of papillomas, or warts, in the oral cavity or other epithelial sites. Young dogs are clinically affected more frequently than older animals. Papillomas develop 4 to 8 weeks after infection, and they typically regress within 4 to 8 weeks (and occasionally longer) after appearance when cell-mediated immune responses cause T-cell infiltration into the wart.[22] Humoral immune responses, although capable of preventing infection, do not seem to play a role in regression of lesions. Although lesions can become quite extensive, especially in the oral cavity, in a given dog, the functional impact of papillomas to the affected animal is usually minimal unless warts develop in locations that lead to dysphagia or respiratory obstruction.

169.10.4 Diagnosis

Diagnosis of COPV is usually based on the observation of characteristic lesions. Viral antigen in lesions can be documented by immunohistochemical techniques, electron microscopy, or PCR-based assays.

169.10.5 Treatment

Because the disease usually regresses spontaneously in the majority of dogs, treatment is not usually needed unless, as noted previously, warts compromise eating or respiration. In such cases, warts can be removed by surgical excision, cryosurgery, or electrosurgery. Refractory cases may benefit from autogenous vaccination in which a wart is removed, a crude vaccine is made, and then injected into the same dog.[22]

169.10.6 Prevention

No preventive vaccine is available for dogs. Dogs that have recovered from COPV are generally immune to reinfection, although occasional dogs, presumably dogs with immune defects, may be susceptible to repeated bouts of clinical disease.

169.11 EMERGING VIRUSES OF INTEREST

169.11.1 West Nile Virus

The West Nile virus (WNV) is a nonenveloped single-stranded RNA virus in the family Flaviviridae. WNV is found worldwide and is maintained in natural settings via transmission from infected to naïve birds via mosquitoes.[23] WNV has emerged recently in the United States as a cause of meningoencephalitis in people and horses, although occasionally other species, including dogs, can develop clinical disease. Epidemiologic studies have demonstrated that seropositive dogs can be found in areas where human infection is endemic.[24] It is currently suspected that nonavian species that become infected from the bite of an infected mosquito do not readily support viral replication leading to a dead-end infection. The pathogenesis of the infection in dogs is unknown. Although to date there have been no published reports describing canine infections, anecdotal reports suggest that clinically affected dogs develop an acute neurologic disease. Definitive diagnosis requires demonstration of viral antigen or nucleic acid in brain tissues. No specific treatments exist beyond supportive therapy, and no approved vaccine is available to prevent infection in dogs.

169.11.2 Bornavirus

The bornavirus (BV) is a enveloped single-stranded RNA virus in the family Bornaviridae. BV causes a fatal disease of the CNS in horses and other animals. Clinical disease in dogs appears to be relatively uncommon. However, reports documenting cases in Europe and Japan are relatively recent, and more cases may emerge as knowledge of the infection increases. The pathogenesis of the disease in dogs is unknown, but clinical signs in dogs have included tremors, salivation, mydriasis, and circling.[25,26] The infection is suspected based on the histopathologic observation of nonsuppurative encephalomyelitis predominantly in gray matter of the brain. Demonstration of viral RNA by in situ hybridization or PCR-based assays has provided definitive diagnosis.

170 CHAPTER • 170 Feline Leukemia Virus

Julie K. Levy

P. Cynda Crawford

170.1 VIROLOGY

Household clusters of lymphoma and lymphocytic leukemia were observed among young cats for many years, but it was not until the discovery of retrovirus particles in a leukemic cat in 1964 that an infectious cause was considered likely. Subsequently, feline leukemia virus (FeLV) was isolated and shown to be capable of transmitting lymphocytic neoplasia among cats. An indirect fluorescent antibody (IFA) test, developed in 1973 to detect antigenemia, made the clinical screening of privately owned cats possible. The mass testing that followed demonstrated that the virus was present at low levels throughout the world's domestic cat population, that it appeared to be spread both vertically (from queen to fetus) and horizontally (from cat to cat), and that infection was associated with a variety of illnesses in addition to neoplasia, including bone marrow suppression and immunodeficiency.

FeLV is a retrovirus; its genetic material is transmitted from host to host as RNA. In infected cells, DNA copies of the virus are transcribed, and it is these copies that are inserted randomly into the host genome. Once this DNA provirus is integrated, cell divisions will result in daughter cells that also contain the viral DNA. The virus encodes several major protein groups: *gag* (group-specific antigens), *pol* (reverse transcriptase), and *env* (envelope). One of the *gag* proteins, p27, is abundant in the plasma of infected cats and in the cytoplasm of individual infected cells. This protein is the basis for most currently used diagnostic tests. The envelope protein gp70 defines the virus subgroup and appears to be important for inducing immunity.

170.2 EPIDEMIOLOGY

The FeLV infection rate of cats is similar throughout the world, ranging from 1% to 8% of healthy cats. Prevalence in feral cats in the southeastern United States is 4%. To date, no large serosurveys have been performed on healthy pet cats in the United States. An infection rate of 21% among symptomatic cats was reported in a survey of 27,976 clinically ill and “at risk” cats, compared with 7% of asymptomatic cats; overall prevalence in this high-risk population was 13%. The study also found that males (15%) were more likely to be infected than females (11%) and that risk of infection was higher in mixed breed (13%) than purebred cats (10%) and outdoor (20%) compared with indoor cats (8%). The prevalence of FeLV was highest in cats aged 1 to 6 years and higher in cats from multicat households than single cat households. Similar results were reported in a survey of cases referred to veterinary medical teaching hospitals from 1972 to 1998. Of 409,417 cats seen at the teaching hospitals, 8756 (2.1%) were diagnosed with FeLV. Prevalence was greatest in male cats, mixed breed cats, and cats aged 2 to 7 years.

Susceptibility to FeLV infection is highest in young kittens, and resistance develops with age. After experimental inoculation with FeLV, 70% to 100% of neonatal kittens remain persistently infected, compared with 30% to 50% of 8-to 12-week-old kittens and 10% to 20% of adolescent and adult cats. This age resistance can be abolished by corticosteroid administration. When susceptible kittens were introduced into households with endemic FeLV, 70% became infected within 5 months, whereas only 18% of adult cats became infected within 5 years under the same circumstances. In nature, the prevalence of anti-FeLV antibodies increases with age, indicating continuous risk of exposure to FeLV throughout life. However, most cases of FeLV are diagnosed in cats less than 4 years of age.

Taken together with the antibody serosurveys, this suggests that exposure to FeLV accumulates with age but that susceptibility to infection simultaneously decreases.

The prevalence of FeLV has been decreasing since the mid-1980s. Widespread test and removal programs have eliminated FeLV from most breeding facilities. Testing of cats at animal shelters prior to adoption and separating infected cats are now common practices. Several FeLV vaccines are available and may also be contributing to the decline of FeLV prevalence. Concurrent with the decline in FeLV is a decline in FeLV-associated diseases, particularly lymphoma.

FeLV infection is slightly more common among male cats than females. Unlike FIV, which is spread primarily by biting during fights, FeLV is passed vertically from infected queens to kittens and horizontally among communal cats with prolonged close contact. The virus is shed in high amounts in the saliva and milk and to a lesser extent in urine and other secretions. Sharing food and water dishes, mutual grooming, and using common litter areas all contribute to virus spread. The wandering and fighting behavior of unneutered males is an additional risk factor for infection among this group.

Infected queens can pass the virus to their offspring in utero. Reproductive failure, taking the form of fetal resorptions, abortions, and neonatal deaths, is common in this situation, although up to 20% of vertically infected kittens may survive the neonatal period to become persistently infected adults. Queens may also infect their kittens after birth via their milk or during grooming. The distinction between vertical transmission from queen to kitten and horizontal transmission among a family group is a somewhat arbitrary one from a clinical perspective. It is common, however, to observe that newborn kittens from persistently or latently infected queens may test negative at birth, only to seroconvert one by one over the following weeks to months. Thus if the queen or any one of her litter tests positive, the entire family should be treated as suspect and isolated from other uninfected cats until their status is resolved.

170.3 DIAGNOSIS

Routine screening for FeLV infection became available when the IFA was developed in 1973. With enzyme-linked immunosorbent assay (ELISA) tests developed several years later, clinicians gained the ability to perform rapid and reliable in-house testing. Later, other immunochromatic lateral flow tests were developed for in-house use. These tests detect the FeLV core protein p27, which is produced abundantly in most infected cats, and are the mainstay of clinical FeLV testing. Immunochromatic tests are performed on serum, plasma, and whole blood samples. User error contributes to false-positive results and is most likely to occur during the washing steps of kits using a micro-well or wand format. The use of membrane-based tests offers the advantage of eliminating separate washing steps and of including both positive and negative controls for each test sample. Some test systems have been developed for use with tears or saliva samples in place of blood. In general, these tests are not as accurate, and, because the consequences of both false-positive and false-negative test results can be disastrous for individual cats or for multiple cat populations, tears and saliva are not recommended for routine screening.

653
654

The IFA detects p27 antigen within the cytoplasm of infected blood cells. Because it requires special processing and fluorescent microscopy, a qualified reference laboratory must perform the IFA. Generally, two or more quality blood or bone marrow smears are air-dried and mailed, unfixed, to the laboratory. The antigen is present at highest concentrations in neutrophils and platelets, and false negatives may result when these two cell lines are deficient. False-positive results may occur when smears are too thick, when background fluorescence is high, and when the test is prepared and interpreted by inexperienced personnel.

Immunochromatic tests, such as ELISA, detect viral antigens circulating freely in the plasma. Because FeLV generally replicates in lymphoid tissue and other sites before the bone marrow, immunochromatic tests may detect

infection a few weeks earlier than the IFA. Some cats are apparently able to clear the infection at this stage and may revert to negative status within a few weeks to months. IFA-positive tests indicate that the bone marrow is infected with FeLV. In this case, most cats remain persistently infected for life. In general, immunochromatic tests are considered to be slightly more sensitive, and the IFA is slightly more specific. With either test, however, the reliability (predictive value) of the test is dependent on the prevalence of infection within different populations of cats. For example, FeLV is present in most cats with thymic lymphoma, so a positive test is likely to be accurate in this situation. In a lower-risk population, such as a closed cattery known to be free of FeLV, a positive test should be viewed with more suspicion and additional confirmatory tests should be performed.

Recently the polymerase chain reaction (PCR) test has been used for the diagnosis of FeLV infection. This test differs from earlier screening tests in that it detects viral nucleic acid sequences (RNA or DNA) instead of protein antigens. PCR may be useful in helping to determine the true status of cats with discordant results from other testing techniques and may be the most sensitive test available. Well-equipped and trained laboratories must perform PCR, because inappropriate sample handling can destroy the delicate nucleic acid material or introduce minute amounts of cross-contamination, leading to either false-negative or false-positive results. PCR is capable of detecting FeLV infection in blood, solid tissues, tissue cultures, and fixed specimens. Commercial FeLV PCR tests detect proviral DNA. FeLV provirus sequences have been detected in both transiently and latently infected cats, as well as in apparently uninfected cats that reside with FeLV-infected cats. This indicates that detectable viral fragments are not always associated with productive infection or clinical disease.

Because no test is accurate 100% of the time, and because various testing modalities target somewhat different specimens and disease stages, it is possible to have discordant test results. The challenge for the clinician is to determine which most likely reflects the true status of the cat. For example, it is possible for infected cats to be antigenemic (viral proteins circulating in the blood) but to have negative virus blood cultures or PCR if the active infection is sequestered in different tissue compartments such as the bone marrow or lymphoid system. In one study of cats positive by ELISA but negative by culture, viral DNA was detected by PCR in 13 of 39 samples, indicating that the cats were most likely infected with FeLV.

Immunochromatic tests are preferred for screening, with the IFA recommended for confirmation of positive results. The combination of routine screening and confirmatory tests will accurately determine the FeLV infection status of most cats. Some animals, however, will have repeatedly discordant test results or occult infections that remain undetected. Rarely, some cats that test negative for viremia have been shown to secrete infectious virus in body fluids such as milk and urine. These cats are infectious to other cats but test negative on routine screening tests. It is particularly difficult to know the true status of cats that have been “transiently” infected and have apparently recovered. In surveys conducted prior to the development of FeLV vaccines, most free-roaming cats acquired anti-FeLV antibodies (evidence of at least transient exposure and infection with the virus). Although almost all of these antibody-positive cats were seronegative for viral antigens, it is not possible to know whether they were truly clear of infection, resistant to further exposure, or latently infected.

The American Association of Feline Practitioners (AAFP) has developed recommendations for testing cats for FeLV. It states that the FeLV status of all cats should be known. Identifying infected cats provides an opportunity to prevent the spread of the disease and to institute appropriate health care for infected cats. The AAFP further recommends testing prior to vaccination for FeLV and retesting cats that become ill. Screening tests detect viral antigens (not antibodies), so neither vaccination nor maternal immunity has an effect on test results. Because cats may be in the early stage of infection at the time of the first test, it is further recommended that a follow-up test be performed at least 1 month after the initial test or after a potential exposure to FeLV. Although this interval is adequate for detection of most infections, periods of up to 6 months between exposure to FeLV and positive test results have been reported.

170.4 PATHOGENESIS

Horizontal transmission of FeLV among susceptible cats occurs most commonly via the oronasal route and by bite wounds. After mucosal or percutaneous inoculation of FeLV, the virus replicates in local lymphoid tissues. From there, infected cells carry the virus to other target tissues, such as thymus, spleen, and lymph nodes. At this stage of acute viral replication, fever, malaise, diarrhea, and leukopenia are common. In addition, generalized lymphadenopathy may be so marked as to be mistaken for lymphoma. The virus later infects the salivary glands and the mucosal glandular epithelium. These sites of infection may secrete most of the infectious virus that is responsible for horizontal transmission. About the same time, bone marrow cells become involved, producing infected leukocytes and platelets that circulate in the blood. In early infection, viral antigens may be detected in the circulation before the bone marrow is infected. This results in discordant test results (immunochromatic tests positive, IFA negative) and explains the slightly higher sensitivity of the immunochromatic tests. Acute infection may follow one of three courses: (1) a vigorous immune response may eliminate the virus, (2) the virus may be sequestered in an inactive latent form, or (3) persistent viremia may develop. It is difficult to differentiate cats that have cleared infection from those that have latent virus. PCR tests on bone marrow may be more sensitive than peripheral blood. Initially, latent infections can reactivate naturally or in response to immune suppression. As time passes, latent infections become more difficult to reactivate, even with the administration of high doses of corticosteroids. By 1 year after infection, reactivation of the virus is considered unlikely. If viremia persists more than 16 weeks, or if the bone marrow is infected, as indicated by a positive IFA test result, chances are high that the cat will remain persistently infected, viremic, and infectious to other cats for the remainder of its life. The ability of FeLV to integrate into the host's own genome is one of the most important factors in persistent infection. Once the pool of stem cells becomes infected, true elimination of the virus becomes unlikely.

654 655

170.5 PREVENTION

When FeLV was first described in the mid-1960s, the highest rates of infection were found in large multicat households and catteries. In contrast, free-roaming cats had lower rates of infection, and cats housed singly indoors were rarely infected. The development of reliable tests allowed cat breeders to implement control programs. A dramatic example was a mandatory test and removal program imposed on all members of a cat breeding society in the Netherlands in 1974. When testing was first implemented, the prevalence of FeLV in purebred catteries was 11%. The rate was reduced to less than 2% within 4 years, and no infected cats have been reported since 1984. Cat fanciers in other countries responded similarly, although on a more voluntary basis, so FeLV is now considered an anomaly in well-run catteries.

The control of FeLV is facilitated by the fragility of the virus outside of the host's body. The virus begins losing viability immediately on dry surfaces and is completely inactivated within a few hours. Environmental contamination from infected cats is easily neutralized by routine disinfectants (detergent, quaternary ammonium, dilute bleach). Indirect exposure between cats at shows or veterinary clinics is not a risk for transmission as long as the cats are not allowed direct contact. FeLV-infected cats do not need to be housed in special isolation rooms at veterinary clinics as long as cats are kept in separate cages. Veterinarians and handlers, however, should take precautions to avoid inadvertent transmission of the virus via contaminated body fluids such as blood, urine, and saliva. Clinical practices that risk nosocomial transmission include serial surgeries performed with the same instruments, reuse of inadequately sterilized needles, reuse of saliva-contaminated endotracheal tubes and dentistry equipment, use of unscreened or latently infected blood donors, and fluid bags shared between patients. The same universal precautions used in human health facilities to prevent the spread of HIV should be incorporated into veterinary practices to prevent the transmission of FeLV and other infectious agents.

FeLV infection is primarily a concern for cats that are social with other cats, because close, intimate contact between cats is optimal for transmission. This type of contact occurs among cats as a result of mutual grooming and sharing of dishes and litter pans. If an FeLV-positive cat is identified in a household, the best method of preventing spread to other cats in the household is to isolate the infected cat in a separate room to prevent the infected cat from interacting with its housemates. Kittens less than 1 year of age are at a greater risk of infection than are adults. If owners choose not to separate housemates, uninfected cats should be vaccinated against FeLV in an attempt to enhance their natural level of immunity. However, it should be understood that FeLV vaccines do not necessarily protect all cats against FeLV infection, and vaccination is not as effective as isolation.

The simplest protection against infection is to keep susceptible cats confined indoors. For cats that are allowed to wander outdoors or that reside with infected cats, vaccination against FeLV may offer protection. Because no standard method exists to evaluate the efficacy of FeLV vaccines in challenge studies, the relative protection offered by the available products is subject to debate. Transient viremia is commonly observed in cats deemed to be protected against persistent viremia in challenge studies, and latent infection can be identified in some of these cats. All FeLV vaccines are inactivated, most contain adjuvants, and they are based on a variety of different virus strains. Vaccines may contain whole virus particles, viral subunits, or recombinants. The emergence of injection-site sarcomas and other problems associated with widespread annual vaccination has led the AAFP to develop revised vaccination guidelines for cats and recommends tailoring vaccine protocols for each patient. The AAFP recommends immunizing only those cats with potential risk of exposure to FeLV (i.e., cats allowed outdoors and cats residing in households with infected cats or with cats of unknown FeLV infection status). Furthermore, it is recommended that all cats be tested for FeLV prior to immunization, because FeLV vaccination of infected cats is not believed to be of benefit. Prevaccination screening also avoids the situation in which an undetected infected cat later develops FeLV-related disease, leading the client to suspect vaccine failure. The AAFP further recommends administering any vaccine with FeLV antigen in the lower left hind leg. This is to aid both the treatment of subsequent sarcomas (by amputation) and to help identify the offending product. It is important to keep detailed medical records of vaccine administration (including date, injection site and route, product, and lot number). The use of peel-off vaccine labels that are placed in the permanent medical record are helpful in this regard. It is also important to report adverse vaccine reactions (please contact the manufacturer).

170.6 CLINICAL DISEASE SYNDROMES

Many cats carry FeLV infections in an asymptomatic state. Clinical signs, when they occur, are varied and nonspecific, depending on the organ system involved and the presence of secondary diseases. In one study of 3712 FeLV-infected cats, 29% were free of clinical signs. This study may underestimate the proportion of asymptomatic cats, because cases were selected based on the presence of illness or a life style at high risk for FeLV infection. Weight loss was the most common clinical sign reported in symptomatic cats (63%), followed by fever (42%), dehydration (35%), rhinitis (18%), diarrhea (17%), conjunctivitis (17%), oral infections (15%), lymphadenopathy (13%), and abscesses (12%). FeLV infection increases the risk for a wide variety of conditions, but it is not always possible to determine whether concurrent diseases are a consequence of FeLV infection or are independent events. Anemia was the most common finding in a study of 8756 FeLV-infected cats seen at veterinary medical teaching hospitals and was diagnosed in 18% of infected cats. Other findings included upper respiratory infections (11%), lymphoma (10%), myeloproliferative diseases (6%), stomatitis (5%), leukopenia (3%), haemotrophic mycoplasmas (3%), lymphadenopathy (3%), and uveitis (2%).

170.6.1 Bone Marrow Disorders

Bone marrow suppression is the most common clinical syndrome associated with FeLV infection and results from primary viral infection of hematopoietic stem cells and from viral infection of stromal cells that constitute the supporting environment for hematopoietic cells. The most common form of FeLV-induced anemia is pure red cell aplasia, a severe nonregenerative anemia associated with marked depletion and maturation arrest of erythroid precursors in the bone marrow. Serum erythropoietin levels are markedly increased, and few cats with FeLV-associated anemia respond to exogenous erythropoietin therapy. A rarely encountered form of FeLV-induced anemia is associated with red blood cell (RBC) macrocytosis. This is believed to represent a virus-induced defect in cell division during RBC maturation.

655

656

Regenerative anemia in FeLV-infected cats, indicated by increased reticulocytes and, in some cases, nucleated RBCs, is less common than nonregenerative anemia and usually occurs in the presence of *Mycoplasma haemofelis* and *Mycoplasma haemominutum* (formerly *Haemobartonella felis*). Approximately one third of cats with immune-mediated hemolytic anemia are FeLV-positive; in some cases, hemolysis precedes the emergence of myeloproliferative disease or lymphoma. Erythemic myelosis is a myeloproliferative disease characterized by high numbers of nucleated RBCs (sometimes exceeding 500 nRBC/100 white blood cells [WBCs]). Although the high number of nucleated RBCs may suggest a regenerative process, the absence of reticulocytes indicates that it is actually a nonregenerative anemia. Erythemic myelosis is resistant to chemotherapy and is virtually always fatal, although affected cats may survive while supported with blood transfusions. Diagnostic evaluation of anemic FeLV-infected cats should include a complete blood count (CBC), reticulocyte count, serum chemistry panel, Coombs' test, and bone marrow evaluation. Examination of blood smears for *Mycoplasma haemofelis* or *M. haemominutum* may be performed, but PCR is more sensitive. If a specific cause for anemia is not determined, treatment should include a course of doxycycline (10 mg/kg orally for a minimum of 21 days) to rule out occult *Mycoplasma* spp. infection. Prednisone at antiinflammatory or immunosuppressive doses or erythropoietin therapy may improve nonregenerative anemia in some cats, but many become transfusion-dependent. Regenerative anemia, which is less common, should be treated as an immune-mediated disease once infectious causes such as *Mycoplasma* spp. and *Babesia* spp. have been ruled out.

FeLV is the most common cause of thrombocytopenia and granulocytopenia in cats. FeLV and myeloproliferative diseases accounted for 44% of cases of feline thrombocytopenia in one report. Cyclic and persistent neutropenia have been observed. The cycles are regular, ranging from 8 to 14 days. In one such cat, platelet count and reticulocyte count also cycled. An immune-mediated mechanism may be involved, because some cats respond to treatment with prednisone. Various cytopenias may wax and wane in FeLV-infected cats, seemingly responding to a variety of therapeutic interventions. Some persistent cytopenias are associated with myelodysplasia and may eventually evolve into a terminal myelodysplastic syndrome or leukemia. In addition to the direct bone marrow suppressive effects of FeLV, nonregenerative anemia, leukopenia, and thrombocytopenia may also be due to secondary effects of the virus, including bone marrow infiltration with lymphoma, leukemia, infectious agents, myelofibrosis, and osteosclerosis.

If cytopenia is severe, or if treatable underlying causes are not identified, therapy may be attempted with hematologic growth factors. Erythropoietin (Epogen, Amgen; 35 to 100 IU/kg subcutaneously every other day to correct anemia, then weekly to sustain PCV) has been of benefit to some cats with FeLV-associated anemia, although most do not respond. Reasons for resistance to erythropoietin include iron deficiency, concurrent infections, FeLV infection of bone marrow stromal cells, and the development of antierythropoietin antibodies. In some nonresponsive cats, repeated blood transfusions may be the only treatment possible. Recombinant human granulocyte colony–stimulating factor (rhG-CSF; Neupogen, Amgen; 5 μg/kg subcutaneously each day)

was developed for neutropenia associated with aggressive human chemotherapy protocols. In cats, rhG-CSF has been used successfully to treat neutropenia due to drug toxicity, infectious diseases, FeLV-associated cyclic neutropenia, and idiopathic causes. Long-term use of the drug in cats is limited by its high cost and the development of neutralizing antibodies against the human protein within a few weeks, but it is often effective for acute or life-threatening neutropenia. Whether antibodies develop in cats that are immune suppressed by FeLV infection or with concurrent use of prednisone is unknown. No growth factor is currently available to stimulate platelet production, and recovery depends on identifying and correcting the underlying cause.

170.6.2 Neoplasia

FeLV-infected cats have sixtyfold increased risk of developing lymphoma compared with FeLV-negative cats. Lymphoma is expected to occur in approximately 25% of cats infected with FeLV, usually within 2 years after diagnosis of the viral infection. Multicentric and mediastinal lymphoma are the most common forms to occur in FeLV-positive cats. Although less common, spinal, renal, ocular and other forms of lymphoma are also reported in young FeLV-infected cats. As the prevalence of FeLV decreased since its discovery, so did its association with lymphoma. Currently, alimentary lymphoma is the most common form diagnosed and a majority of affected cats are now middle-aged or geriatric and FeLV negative. FeLV may also have a role in lymphoma development in some cats that test negative for infection. FeLV genetic sequences and antigens have been identified in the tumors of some cats with negative FeLV blood tests. FeLV-negative housemates of infected cats have a fortyfold increased risk of lymphoma compared with cats that do not reside with infected cats. Although some reports suggest that concurrent FeLV infection is associated with reduced rate or duration of remission in cats treated for lymphoma with chemotherapy, other reports found no such effect.

Myelodysplasia (preleukemia) is characterized by nonregenerative anemia accompanied by abnormalities in cellular maturation in the bone marrow. Granulocytopenia and thrombocytopenia may also occur. Most cats are positive for FeLV. Bone marrow is usually hypercellular, and many samples also exhibit myelofibrosis. Blast cells comprise less than 30% of the marrow elements, distinguishing myelodysplasia from leukemia. Progression to acute leukemia is common and may occur within weeks to months after the diagnosis of myelodysplasia. Treatment with immunosuppressive doses of corticosteroids and blood transfusions may palliate clinical signs, but the prognosis is poor for most cats that have cytopenias due to myelodysplasia. Nearly all cats with acute nonlymphoid leukemia (ANLL or acute myeloid leukemia) are FeLV positive. These leukemias can involve erythroid elements (erythemic myelosis, erythroleukemia, reticuloendotheliosis), myeloid elements (granulocytic, monocytic, or myelomonocytic leukemia), or megakaryocytes. Stem cell involvement may result in a sequential expression of leukemia of various cell lines. Prognosis is grave for ANLL because chemotherapy does not appear to alter the course. Most cats are euthanized within days to weeks of diagnosis. Heavy infiltration of bone marrow (and frequently other organs) with lymphoblasts characterizes acute lymphocytic leukemia (ALL). ALL is often accompanied by anemia and circulating blasts. Most cats with ALL are FeLV-positive. Differentiating ALL from advanced lymphoma can be difficult, although the treatment for both forms of lymproliferative disease are similar. Chronic lymphocytic leukemia is uncommon in the cat, tends to occur in older FeLV-negative cats, and carries a better prognosis than ALL. Hypereosinophilic syndrome, polycythemia vera, and multiple myeloma are proliferative hematologic disorders that are not associated with FeLV infection.

Although lymphoid and hematologic malignancies are the most common forms of neoplasia associated with FeLV, viral infection is also associated with specific tumors of other organ systems. Osteochondromatosis is a syndrome usually observed in young FeLV-infected cats in which multiple lesions affect the skeleton; solitary lesions in older cats are usually not associated with FeLV. Olfactory neuroblastoma is a rare FeLV-associated tumor involving the nasal cavity with frequent invasion through the cribriform plate. Multiple subcutaneous

fibrosarcomas require coinfection of FeLV and feline sarcoma virus, which arises as a recombination between FeLV and cellular oncogenes. Similar to the reduction in observed cases of lymphoma, the decreasing prevalence of FeLV has paralleled a decrease in cats diagnosed with ANLL and other FeLV-associated malignancies. Diagnosis and treatment of FeLV-associated neoplasms are discussed in detail in Chapter 181.

170.6.3 Secondary Infections

Diseases associated with immune suppression account for much of the morbidity and mortality in FeLV-infected cats. Thymic atrophy and depletion of lymph node paracortical zones are common findings, particularly in cats infected as kittens. Neutropenia and lymphopenia may further exacerbate immune suppression. Several immune function tests have been reported to be abnormal in FeLV-infected cats, including poor response to T-cell mitogens, prolonged allograft rejection, reduced immunoglobulin production, depressed neutrophil function, complement depletion, and cytokine dysregulation.

Many reports exist of FeLV-infected cats having concurrent bacterial, viral, protozoal, and fungal infections; however, few studies prove these cats have a higher rate of infection than FeLV-negative cats or that they have a less favorable response to therapy. Thus, although FeLV is well known to suppress immune function, it should not be assumed that all concurrent infections are a result of FeLV infection. The most common secondary infections associated with FeLV are respiratory viruses that persist longer and cause greater illness than observed in immune competent cats. *Mycoplasma* spp. infections (haemobartonellosis), which may be clinically silent in healthy cats, are more likely to be associated with severe hemolytic anemia in FeLV-coinfected cats. Cats residing in households endemic for both FeLV and coronavirus are more likely to develop fatal FIP if they are infected with FeLV. Treatment-resistant dermatophytosis and acute generalized toxoplasmosis are also associated with FeLV infection.

170.6.4 Miscellaneous Disorders

A variety of other disorders are associated with FeLV infection. Reproductive failures have been associated with abortion due to transplacental infection of fetuses and endometritis. Glomerulonephritis has been a histologic finding in FeLV-infected cats, but is not usually clinically significant. Generalized lymphadenopathy has been observed in several young cats and may be mistaken for lymphoma. The lymph node enlargement usually resolves after several months without treatment. A “panleukopenia-like syndrome” of FeLV mimics feline parvovirus infection and is characterized by panleukopenia, crypt necrosis, and high mortality. In some cats, parvovirus is identified as a coinfection, suggesting that FeLV may enhance the susceptibility of adult cats to parvoviral enteritis. Neurologic infection has been reported to cause urinary incontinence and papillary spasm leading to *D*-shaped pupils and anisocoria. FeLV-associated myelopathy results in vocalization, hyperesthesia, and paresis progressing to paralysis. Lymphocytic-plasmacytic stomatitis, although more common in cats infected with FIV, is also increased in FeLV-infected cats.

170.7 TREATMENT OF FELV-INFECTED CATS

Adherence to the AAFP guidelines to test all cats for FeLV is likely to result in the identification of many asymptomatic cats. Early identification allows steps to prevent the spread of infection and to optimize the health of infected cats. The AAFP recommends that cats infected with FeLV be confined indoors to prevent spread to other cats in the neighborhood and exposure of affected cats to infectious agents carried by other animals. As for all cats, good nutrition and husbandry are essential to maintaining health. Cats should be fed a nutritionally balanced and complete feline diet. Raw meat and eggs and unpasteurized dairy products should be avoided, because the risk

of food-borne bacterial and parasitic infections is greater in immune-suppressed individuals. A program for routine control of gastrointestinal parasites, ectoparasites, and heartworms, where applicable, should be implemented.

Cats infected with FeLV should receive wellness visits at least semiannually to promptly detect changes in their health status. Veterinarians should obtain a detailed history to help identify problems requiring more intensive investigation and perform a thorough physical examination at each visit. Special attention should be paid to the oral cavity, because dental and gum diseases are common in affected cats. Lymph nodes should be identified and carefully evaluated for changes in size and shape. The skin should be examined closely for evidence of external parasitic infestations and fungal diseases. The body weight should be recorded, because weight loss is often the first sign of deterioration in a cat's condition. A CBC should be performed semiannually for FeLV-infected cats, because of the high risk of hematologic disorders. Serum biochemical analyses and urinalyses should be performed yearly; urine samples should be collected by means of cystocentesis so that bacterial cultures can be performed, if necessary. Fecal examinations should be considered for cats with a history of possible exposure to internal parasites or with a history of GI tract disease.

Vaccination programs to prevent common, serious infectious diseases should be maintained. In general, vaccination programs for infected cats are similar to those for uninfected cats. Rabies vaccines should be given in accordance with state and local regulations. Feline viral rhinotracheitis-calicivirus-panleukopenia vaccines should be given in accordance with the AAFP guidelines (i.e., routine primary vaccination, followed by a booster vaccination 1 year later and every 3 years thereafter). Some clinicians recommend that only inactivated vaccines be used in infected cats. However, little evidence indicates that such cats are at increased risk of adverse effects with modified-live virus (MLV) vaccines. FeLV vaccines are of no benefit in and should not be given to FeLV-infected cats. Other vaccines should be evaluated carefully before being administered. Sexually intact cats should be sterilized to reduce stress associated with aggression, estrus, and mating behaviors. Neutered animals are also less likely to roam outside the house or to interact aggressively with their housemates. Surgery is generally well tolerated by infected cats that are not showing clinical signs of disease. Perioperative antibiotic administration may be considered for cats undergoing dental procedures and invasive surgeries.

Illnesses in cats infected with FeLV are often secondary diseases acquired because of immune dysregulation and not the direct effects of the FeLV infection. Prompt and accurate identification of secondary illnesses is essential to allow early therapeutic intervention and a successful outcome. Therefore intensive diagnostic testing may proceed earlier in the course of illness for infected cats than might be recommended for uninfected cats. Many cats infected with FeLV respond as well as their uninfected counterparts to appropriate treatment strategies, although a longer or more aggressive course of treatment may be needed. Owners should be forewarned and clinicians should not be discouraged if a response to treatment takes longer than expected. As in the case of asymptomatic cats, corticosteroids and other immunosuppressive drugs should be administered only to those patients with a clear indication for their use.

170.8 IMMUNE-MODULATOR AND ANTIVIRAL THERAPY

The evaluation of anti-FeLV therapies is hampered by the lack of well-controlled clinical trials in which new treatments are compared against standard care or placebo. Host factors, such as the age of the cat at the time of infection, genetics, immune function, and concurrent diseases interact with viral factors, including virus strain, dose, and route of infection in determining the clinical outcome of infection. The marked natural variation in disease expression among infected cats makes it risky to predict which cats will have rapid progression of disease and which will be long-term survivors. In addition to host and viral factors that affect infected cats, the attitude and motivation of both the owners and the treating veterinarians can have a profound influence on the clinical outcomes. Immune modulators are suggested to benefit FeLV-infected cats by restoring compromised immune

function, thereby allowing the patient to control the virus and recover from associated clinical syndromes. Antiviral agents directly inhibit virus infection and replication.

170.8.1 Immune-Modulating Agents

Acemannan (Carrisyn, Carrington Laboratories) is a complex carbohydrate (mannan) polymer derived from the aloe vera plant. In one uncontrolled open-label trial, 50 cats with natural FeLV infection were treated with acemannan (2 mg/kg intraperitoneally every week for 6 weeks). Whether concurrent supportive care was permitted was not described. At the end of the 12-week study period, nine cats had been excluded from evaluation. Of the remaining 41 cats, 29 (71%) were known to be alive. All cats remained ELISA-positive for FeLV antigen, and there were no significant changes in clinical or hematologic scores. Because the study did not include a control group, and because clinical and laboratory evaluations failed to document improvement from pretreatment evaluations, it is difficult to determine whether the use of acemannan improved the outcome of infection in treated cats.

Propionibacterium acnes (ImmunoRegulin, ImmunoVet) is a killed bacterial product. No prospective studies have been reported for use in FeLV-infected cats, but veterinarians have described their clinical experiences in anecdotal reports. In one discussion, 76 clinically ill cats with natural FeLV infections were treated with ImmunoRegulin (0.25 to 0.5 mL intravenously twice weekly, then every other week for 16 weeks) and supportive care, including prednisone, antibiotics, and vitamins. Although no specific clinical and laboratory evaluations were discussed, 55 (72%) of the cats reportedly became seronegative for FeLV antigens and survived for an unspecified period of time.

Interferons (IFNs) have been used as antiviral agents (at high doses) and as immune modulators (at low doses). Anecdotal reports of beneficial responses in cats with FeLV infection treated with low doses administered orally (0.5 to 30 U orally each day) have been described. In a review of more than 100 FeLV-infected cats treated with various protocols for low-dose rhIFNα in combination with antibiotics, blood transfusions, fluids, and other supportive care, it was recommended to treat cats with 15 to 30 U orally each day for 7 days on alternate weeks. The mechanism by which oral rhIFNα acts is unknown, but it is not believed to be present in the blood or oral cavity in concentrations high enough to exert a direct antiviral effect. In one study, rhIFNα failed to improve hematologic or lymphocyte subset abnormalities in cats with chronic FeLV infection. rhIFNα (Roferon, Hoffman LaRoche; Intron A, Schering-Plough) is supplied in 3,000,000 U vials. The protocol for diluting the drug for oral use is (1) mix 3,000,000 U in 1 liter sterile saline; (2) freeze in 1 or 10 mL aliquots; (3) as needed, thaw aliquots and mix into the working solution by further diluting into 100 mL (1 mL aliquot) or 1000 mL (10 mL aliquot); (4) the final working concentration of 30 U/mL is considered an appropriate cat dose. This working solution is reportedly stable in the refrigerator for 2 months.

Staphylococcus protein A (SPA, Sigma) is a bacterial polypeptide product purified from the cell wall of *Staphylococcus aureus* Cowan I. A variety of SPA sources and treatments have been used in FeLV-infected cats. In some studies, a high rate of tumor remission and conversion to FeLV-negative status was observed, whereas in others, responses were less dramatic and short-lived. In a study of kittens with experimental FeLV infection, treatment (20 μg/2.75 kg intraperitoneally twice weekly for 8 weeks) neither reversed viremia nor improved humoral immune function. A recent double-blind controlled trial compared treatment of naturally infected cats with SPA, rhIFNα, SPA+rhIFNα, or placebo. There were no significant differences in survival, hematology, or clinical findings.

PIND-ORF (Baypamune, Bayer) is derived from an inactivated *Parapox ovis* virus and is proposed to induce nonspecific or “para” immunity. After reports of curing infection and disease in hundreds of FeLV-infected cats, Baypamune (1.0 mL subcutaneously 1 to 3 times weekly for 4 to 30 weeks) quickly became the most

commonly used treatment for FeLV infections in Europe. In one of the only large-scale double-blind, placebo-controlled clinical trials of an immune modulator reported to date, 150 cats with natural FeLV infection were randomized to receive Baypamun (1.0 mL subcutaneously twice for 1 week, then weekly for 6 weeks) or placebo. There were no significant differences in clinical score, hematology score, lymphocyte subsets, FeLV p27 concentration, pterin concentration, reversion to negative status, or survival between the groups. Overall, between 7% and 12% of the cats in both groups became negative for FeLV p27 antigen. This study demonstrates the marked differences that can be observed in uncontrolled or retrospective studies compared with randomized, controlled clinical trials.

170.8.2 Specific Antiviral Agents

AZT/Zidovudine (Retrovir, GlaxoSmithKline) is the most widely used antiviral agent for both human and feline retroviral infections. It is a nucleoside analog inhibitor of the viral reverse transcriptase enzyme, preventing conversion of viral RNA into DNA, which would then enter the host genome. Only 1 controlled clinical trial has been reported in which cats with natural FeLV infections were treated with AZT. In this study, 32 FeLV-infected cats, all with chronic oral inflammation (stomatitis), were treated with AZT (5 mg/kg subcutaneously twice a day) or placebo for 3 weeks in a double-blind design. No other treatments were permitted. AZT-treated cats had improved stomatitis score and decreased FeLV p27 antigenemia compared with placebo. Previously, AZT was recommended at 15 mg/kg twice a day. The dose of 5 mg/kg twice a day used in this study was associated with decreased hematologic toxicity and cost.

Recombinant human interferon alpha (rhIFNαIntronA, Schering-Plough; Roferon, Hoffman LaRoche) has potent antiviral activity, preventing final virion assembly and budding. When administered to cats with experimental FeLV infection, rhIFNα (10^4 to 10^6 U/kg subcutaneously each day) effectively reduced FeLV p27 antigenemia. The effect was most rapid and complete in the high-dose treatment group. However, neutralizing antibodies developed against the human protein and appeared earliest in the high-dose group. Thus, the authors concluded that the intermediate dose of 10^5 U/kg provided the most beneficial balance of efficacy and duration of action, which persisted approximately 50 days until antibodies inhibited activity. Interestingly, the addition of AZT to a rhIFNα treatment did not enhance the antiviral effect in this study of chronically infected cats as it did in a study of FeLV prophylaxis. The cats in this study were healthy, so a clinical benefit could not be assessed. Theoretically, the observed suppression of virus load could benefit FeLV-infected cats because the immune system may achieve some level of reconstitution during this period. A recombinant feline rhIFNα omega product (10^3 to 10^6 U/kg subcutaneously each day) from Japan (INTERCAT, Toray) failed to decrease FeLV p27 levels or prevent lymphoma in experimentally infected cats. Recently, rfaIFN omega became available in Europe (Virbagen Omega, Virbac) and is approved for the treatment of parvoviral enteritis in dogs. The manufacturer reports that clinical condition and the proportion of cats surviving ±1 year are increased in FeLV-infected cats treated with IFN omega (10^6 U/kg subcutaneously each day for 5 days on day 0, day 14, and day 60) compared with cats treated with placebo.

171 CHAPTER • 171 Feline Immunodeficiency Virus Infection and Related Diseases

Katrin Hartmann

In 1986, feline immunodeficiency virus (FIV), a T-lymphotropic lentivirus causing an acquired immunodeficiency syndrome (AIDS) in domestic cats, was isolated in Davis, California. FIV shares many morphologic and biochemical properties with human immunodeficiency virus (HIV) but is antigenetically distinct. The pathogenesis of both virus infections is characterized by a long period of clinical latency during which immune function gradually deteriorates. Triggered by factors as coinfections, ultimately the immunodeficiency syndrome develops and is accompanied by opportunistic infections, myelosuppression, tumors, or neurologic disease. No evidence links FIV infection to any human disease, including AIDS. Investigations have failed to identify antibodies in people that have been bitten by infected cats or who have inadvertently injected themselves with virus-containing material.

FIV has been detected worldwide in domestic cats. In the United States, antibody prevalence ranges from 1% to 24%; prevalence is higher in cats at high risk of exposure and in sick cats. In large surveys of stray and feral cats in the United States, overall percentage rates of 2% to 4% are reported. There seem to be no regional difference in the United States; in Europe, however, infection rates vary significantly (e.g., from 2% in Germany and The Netherlands to over 30% in Italy). Cats that are free roaming in areas of high cat density have an increased opportunity for exposure, largely because bite wounds are the most important mode of transmission. Male cats are infected 2 to 4 times more frequently than females, and the prevalence is higher in adult cats. In a survey study of 826 naturally FIV-infected cats examined at North American Veterinary Teaching Hospitals, 80% were male and 78% were at least 2 years old at the time of presentation. Adult male cats living outdoors consistently compose the majority of FIV-infected cats, and the risk is highest for sexually intact males.[1,2]

171.1 PATHOGENESIS

The pathogenesis of FIV infection is not completely understood. Despite the generation of antibodies and a strong cellular immune response, a latent infection arises and infection cannot be cleared. The hallmark of FIV pathogenesis is the progressive disruption of normal immune function. FIV replicates in $CD4^+$ and $CD8^+$ lymphocytes, B lymphocytes, macrophages, astrocytes, and microglia cells. Ability to replication in different cell types is thought to be associated with use of different cellular receptors and to be responsible for different clinical manifestations of FIV infection. Virus replication in cells of the monocyte and macrophage lineage can result in central nervous system (CNS) disease.[3]

FIV can be isolated from lymphocytes, at the earliest, 10 to 14 days after infection. Viremia rapidly increases until day 21, peaks between weeks 7 and 8, and then decreases gradually until the virus load increases in the terminal stage. Conversely, when the virus peaks, the number of $CD4^+$ cells decreases. In the first few weeks of infection, numbers of both $CD4^+$ and $CD8^+$ cells decline. The initial lymphopenia is followed by a strong immune response characterized by the production of anti-FIV antibodies and a rebound in $CD8^+$ cells above pre-infection levels. This results in a persistent inversion of the CD4/CD8 ratio. Over time, numbers of both $CD4^+$ and $CD8^+$ cells gradually decline. Decrease of $CD4^+$ cells is caused by a shortened life span in infected lymphocytes and apoptosis of uninfected cells. In HIV, distinctive clinical stages can be defined based on absolute $CD4^+$ cell count. A $CD4^+$ cell count of 200/μL or less is considered an AIDS-defining condition. It is more difficult to assign clinical stages of disease to cats based on $CD4^+$ cell counts, mainly because FIV appears to be less pathogenic

than HIV. Although chronic inflammatory conditions and opportunistic infections are more common in cats with low $CD4^+$ cells, other cats with low counts appear to remain healthy.

In addition to the quantitative decrease in $CD4^+$ cells, FIV-infected cats show dysfunction of immune cells (e.g., loss of ability of lymphocytes to proliferate in response to stimulation) and a significant perturbation of cytokine production. Cell-mediated immunity is more profoundly affected than humoral immunity. Despite being target cells of viral infection, no changes in number or proportions of B cells occur after FIV infection.[2] Consequently, chronic inflammatory conditions, neoplasia, and infections with intracellular organisms are more common than infections controlled by antibodies. FIV-infected cats respond adequately to vaccinations and frequently develop a polyclonal hypergammaglobulinemia characteristic of nonspecific stimulation of humoral immunity.

171.2 CLINICAL SIGNS

FIV infection progresses through several stages, much like HIV infection in humans. Clinical stages in cats include an acute phase, a clinically asymptomatic phase of variable duration, and a terminal phase. Attempts have been made to define the clinical course in different stages analogous to those of HIV infection; however, often no sharp distinction is seen between the phases in cats, and not all stages will always be apparent. The clinical disease caused by FIV is dependent on age and health at the time of infection, dose and route of virus inoculation, virus strain, and immunologic competence of the cat. Experimental infections of cats in different environments have helped to differentiate between primary viral effects and syndromes that develop only in the presence of cofactors. During a 4-year follow-up period, both SPF and random source FIV-infected cats experienced immunodeficiency with progressive inversion of the CD4/CD8 ratio. The random source cats went on to an AIDS-like syndrome characterized by stomatitis, recurrent respiratory disease, diarrhea, and weight loss. In contrast, SPF cats developed lymphoma or neurologic disease believed to be caused by direct viral effects and not to be the consequence of immunodeficiency.[2]

Many FIV-infected cats are healthy; others have a history of recurrent illnesses. In a follow-up study of naturally FIV-infected cats, 18% of infected cats died within the first 2 years of observation (5 years after the estimated time of infection) and 18% developed increasingly severe disease. However, more than 50% of infected cats remained asymptomatic during the 2 years.[1] In a survey study of 826 naturally FIV-infected cats examined at North American Veterinary Teaching Hospitals, the most common disease syndromes were stomatitis, neoplasia (especially lymphoma and cutaneous squamous cell carcinoma), ocular inflammation (uveitis and chorioretinitis), anemia and leukopenia, opportunistic infections, renal insufficiency, lower urinary tract disease, and endocrinopathies such as hyperthyroidism and diabetes mellitus.[2] Some of these diseases are most likely associated with the older age at which these cats presented (e.g., endocrinopathies, renal insufficiency) than with their FIV infection.

171.2.1 Stomatitis

Chronic ulceroproliferative stomatitis is the most common disease syndrome found in cats naturally infected with FIV, affecting up to 50% of infected cats. It characteristically originates in the fauces and spreads rostrally, especially along the maxillary teeth. Lesions are often painful and tooth loss is common. Severe stomatitis can lead to anorexia and emaciation. Histologically, the mucosa is invaded by plasma cells and lymphocytes, accompanied by variable degrees of neutrophilic and eosinophilic inflammation. The cause of the syndrome is uncertain, but the histologic findings suggest an immune response to chronic antigenic stimulation or immune dysregulation. Circulating lymphocytes of cats with stomatitis have greater than normal expression of

inflammatory cytokines,[2] further implicating immune activation in the pathogenesis of this condition. Concurrent calicivirus infection is often identified in the oral cavity of cats with FIV-associated stomatitis and may be one of the infectious cofactors. Other infectious agents, including *Trichomonas*, *Candida*, or *Bartonella* infections, may also play a role.

171.2.2 Neurologic Disease

Both central and peripheral neurologic disease are common in HIV-infected humans, and the same is true of FIV. Dementia of human AIDS is often characterized by a slight decline in cognitive ability or behavior, changes that may be too subtle to recognize in cats. About 5% of clinically affected FIV-infected cats have neurologic disease as a predominant clinical feature. Although the majority of FIV-infected cats do not show clinically observable neurologic signs, a much higher proportion of infected cats exhibit microscopic CNS lesions. Brain lesions may occur in the absence of massive infection, and abnormal neurologic function has been documented in FIV-infected cats with only mild to moderate histologic evidence of inflammation.[1]

Uncommonly, neurologic signs may be caused by opportunistic infections such as toxoplasmosis, cryptococcosis, or feline infectious peritonitis (FIP). Mostly abnormal neurologic function is the result from a direct effect of the virus on CNS cells. Neurologic expression of FIV infection is highly strain dependant. The virus infects the brain early, with virus-induced CNS lesions sometimes developing within 2 months of experimental infection.[1] Neurologic abnormalities seen in naturally infected cats tend to be more behavioral than motor. Twitching movements of the face and tongue, psychotic behavior, compulsive roaming, dementia, loss of bladder and rectal control, and disturbed sleep patterns have been observed. Other signs described include nystagmus, ataxia, seizures, and intention tremors. In addition, sensitive electrodiagnostic tests such as nerve conduction velocity and brain stem auditory evoked potentials have detected abnormalities in clinically normal FIV-infected cats. Pathologic findings include the presence of perivascular infiltrates of mononuclear cells, diffuse gliosis, glial nodules, and white matter pallor. These lesions are usually located in the caudate nucleus, midbrain, and rostral brain stem.[1] Microglia and astrocytes are infected by FIV. The virus does not infect neurons; however, neuronal death has been associated with FIV infection. In particular, forebrain signs are often a result of direct neuronal injury from the virus. The mechanism of neuronal damage by FIV is unclear but may include neuronal apoptosis, effects on the neuron-supportive functions of astrocytes, toxic products released from infected microglia, or cytokines produced in response to viral infection. In vitro studies support the hypothesis that FIV infection may impair normal metabolism in CNS cells, particularly astrocytes.[1] Documented abnormalities of astrocyte function include altered intercellular communication, abnormal glutathione reductase activity that could render cells more susceptible to oxidative injury, and alterations in mitochondrial membrane potential that disrupt energy-producing capacities of the cell.[4] Astrocytes are by far the most common cell type of the brain and are important in maintaining CNS neuronal microvascular microenvironment. One of the most important functions of astrocyes is to regulate the level of extracellular glutamate, a major excitatory neurotransmitter that accumulates as a consequence of neuronal activity. Excessive extracellular glutamate often results in neuronal toxicity and death. FIV infection of feline astrocytes can significantly inhibit their glutamate-scavenging ability, potentially resulting in neuronal damage.[4,5]

171.2.3 Tumors

FIV-infected cats have a higher incidence of certain types of tumors and are five times more likely to develop lymphoma or leukemia than noninfected cats, compared with a sixty-twofold increase in cats infected with feline leukemia virus (FeLV).[4] In contrast to lymphoma in FeLV-infected cats that is primarily of T cell origin,

the phenotype of FIV-associated lymphoma is mainly B cell. Other neoplastic diseases in FIV-infected cats include squamous cell carcinoma, fibrosarcoma, mast cell tumor, myeloid tumor, and leukemia. It is not known exactly how FIV is associated with these cancers. Lentiviruses are not directly oncogenic. Because increasing age is a risk factor both for FIV infection and development of neoplasia, it is difficult to determine the exact role of FIV in carcinogenesis. Infection with immunosuppressive lentiviruses is associated with increased cancer risk, but most studies suggest indirect mechanisms. With the exception of one recently published case,[5] integrated FIV sequences cannot been detected in lymphoma cells, suggesting that, unlike FeLV, the role of FIV in lymphoma development is generally indirect. Several theories exist concerning the association of tumors with FIV infection. FIV might increase cancer incidence by decreasing tumor immunosurveillance mechanisms. It might promote tumor development through the immunostimulatory effects of replicating in lymphocytes. Finally, it might impair immunologic control of FeLV infection or of transformed lymphoid cells.

660

661

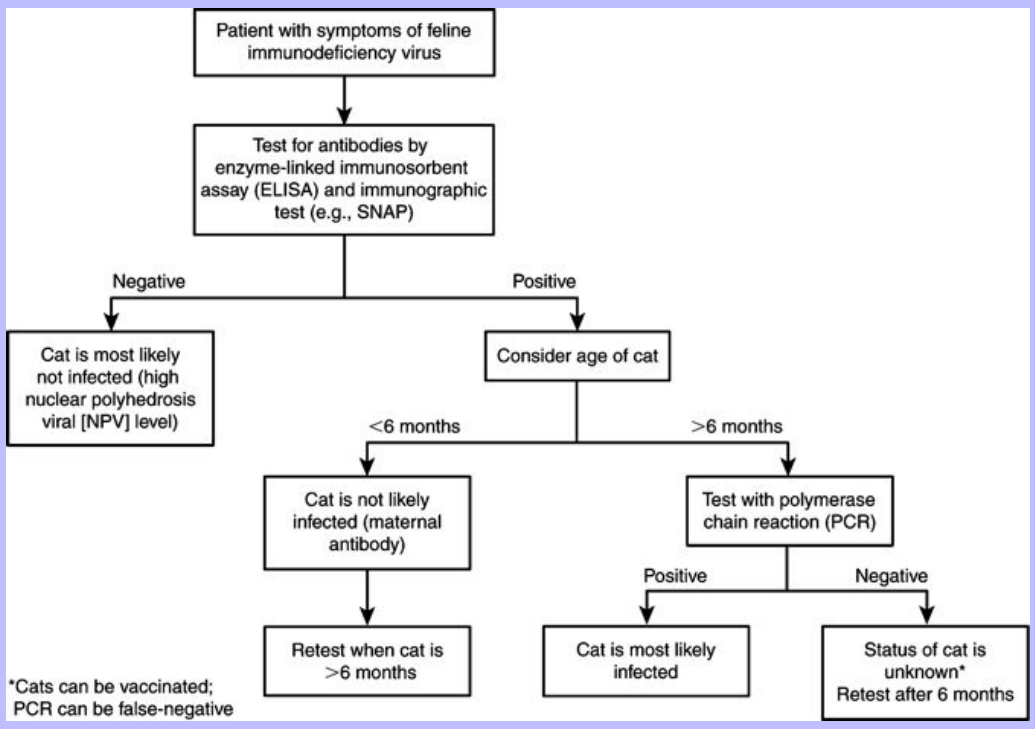
171.3 DIAGNOSIS

Currently available tests for FIV infection rely on the detection of antibodies to FIV (Figure 171-1). In contrast to FeLV, FIV antigen concentration in blood is too low to be detected. FIV-infected cats do, however, usually develop high levels of FIV-specific antibodies, and FIV produces a persistent infection from which cats do not recover. Therefore FIV-specific antibody detection was effectively used for diagnosis, and the presence of antibodies was predictive of infection in cats older than 6 months of age. In kittens less than 6 months of age, antibody tests must be interpreted carefully because kittens acquire anti-FIV antibodies by passive transfer in colostrum from infected or vaccinated mothers. It is very rare for kittens to become infected from their mothers under natural circumstances, so most kittens (that are truly uninfected) initially testing positive will eventually test negative when their maternal antibodies wane.

Antibodies to FIV can be detected by immunochromatographic tests like enzyme-linked immunosorbent assay (ELISA). These tests can produce false-positive results for a number of reasons, a fact that is of major importance in areas with low FIV prevalence (e.g., United States, Northern European countries). Therefore positive results should be confirmed with a Western blot or at least with a second immunochromatographic test.

Interpretation of positive FIV tests is unfortunately confounded by a recently approved vaccine (on the U.S. market) that interferes with all tests relying on antibody detection, including the confirmatory Western blot. This vaccine induces broad spectrum antibody production to FIV proteins and results in long-lasting titers. These antibodies are indistinguishable from those detected in infected cats. After vaccination a cat will test positive for at least 12 months and will transfer antibodies to kittens through colostrum. Polymerase chain reaction (PCR) and virus isolation have been suggested as alternative testing methodologies. Virus isolation is possible over the whole infection period, but is time-consuming, expensive, and requires expertise; therefore it is not practical for routine diagnosis. PCR is a very sensitive and specific method when used in experimental conditions. If appropriately inactivated the current vaccine should not result in viral genome production and should not interfere with PCR assays. PCR requires specialized equipment, is not available for patient-side testing, and is performed only by specialized laboratories. Current PCR tests in the field are not standardized, and information about sensitivity, specificity, and overall diagnostic performance in naturally infected cats is not available. Due to the marked variability of the viral genome in the field, failure rates to detect FIV infection by PCR of up to 50% have been reported; therefore false-negative results are common. Another concern is that the high sensitivity of PCR may lead to false positive results if even minor contaminations occur during handling of samples.[3,5]

Figure 171-1 Algorithm for feline immunodeficiency virus.



171.4 PREVENTION

FIV infection can be best prevented by keeping cats out of environments that encourage high-risk behavior. Cats should be neutered and not be exposed to untested homeless, feral, abandoned, or stray cats.

Development of an effective vaccine is difficult because of the nature of the retrovirus-host interaction and the relatively poor immunogenicity of lentiviral antigens in inducing vaccinal immunity. Cats typically mount a marked antibody response after exposure to FIV, but these antibodies are unable to clear infection. Many approaches have been taken toward the development of an effective vaccine against FIV, but the same hurdles facing HIV prevention also apply to FIV. Both viruses have an error-prone RT, which enhances the mutation rate of replicating virus and increases the opportunity for escape from immune surveillance. The viruses can even take advantage of specific antibody formation, using antibodies to enhance pathogenicity or to enter cells via immune complexes. To date, no vaccine approach has been completely successful in preventing infection, and in some cases immunization paradoxically enhanced viral replication and disease expression. Another major obstacle in designing an effective vaccine against FIV infection is the large genetic diversity among viral isolates. Five known subtypes of FIV exist, and sequence divergence ranges from 2% to 15% within a subtype (between subtypes it ranges up to 26%). The new vaccine (Fel-O-Vax FIV®) is a dual-subtype vaccine containing inactivated FIV subtype A and subtype D with an adjuvant. The combination of two genetically distinct subtypes elicits strong anti-FIV cellular immunity and broad-spectrum virus-neutralizing antibodies, but the range of protection is still unknown. This vaccine has not yet been field tested against natural FIV infection, and protection against the frequently found subtype B viruses (in USA and in Europe) is uncertain.[3,5]

171.5 TREATMENT

In most naturally infected cats, FIV infection does not cause a severe clinical syndrome. With proper care, FIV-infected cats can live many years and, in fact, may die in older age from causes unrelated to their FIV infection. Survival time is long and quality of life is usually good. The most important life-prolonging advice is to keep FIV-infected cats strictly indoors, not only to prevent spread to other cats but also to prevent exposure of the immunosuppressed cat to infectious agents carried by other animals. Secondary infections not only cause clinical signs in FIV-infected cats but also lead to progression of FIV infection.

171.5.1 Antiviral Chemotherapy

Clinical use of antiviral drugs is still not very common in veterinary medicine. With the exception of feline interferon-ω now on the market in Japan and some European countries, no antiviral drugs are licensed for veterinary use; therefore human drugs must be used in animals. Most antivirals are specifically intended for treatment of HIV infection, and many of those can be used to treat FIV infection because most enzymes of FIV and HIV have similar sensitivities to various inhibitors. In cell culture and experimental studies, several compounds have been shown to be active against FIV. However, many of these studies used FIV as a model for screening new compounds for HIV, and most of these drugs will never be accessible to veterinarians. Unfortunately, to date the drugs available to cats are limited, and only few controlled studies have been performed to support their use.

Licensed antiviral compounds that have been used in FIV-infected cats include zidovudin (3′-azido-2′,3′-dideoxythymidine, AZT), phosphonoformate (foscarnet), ribavirin, and interferons (human interferon-α, feline interferon-ω). Foscarnet and ribavirin are relatively toxic in cats, and their use is limited in feline medicine. AZT is the most thoroughly studied anti-FIV drug. It is a nucleoside analogue (thymidine derivative) that blocks the RT of retroviruses. It is integrated in the developing DNA strand and thus inhibits new infection of cells but not replication of viruses already present in infected cells. AZT reduces plasma virus load and improves the immunologic and clinical status of FIV-infected cats resulting in increased survival time. In a placebo-controlled trial, AZT improved stomatitis in naturally infected cats. It is used at a dose of 5 to 10 mg/kg every 12 hours (orally or subcutaneously). During treatment, regular blood cell counts are necessary because nonregenerative anemia is a common side effect, especially if the higher dose is used. Cats with myelosuppression should not be treated. Studies in which cats were treated with AZT for 2 years demonstrated that AZT is well tolerated in most FIV-infected cats. Some cats developed a mild decrease in hematocrit initially in the first 3 weeks that resolved even if treatment was continued. If hematocrit drops below 20%, discontinuation of AZT is recommended and anemia usually resolves within a few days. Unfortunately, as in HIV, AZT-resistant mutants of FIV can arise as early as 6 months of treatment.

Interferons have an immunomodulatory effect and a direct antiviral effect by inducing an antiviral state of cells that protects against virus replication. Human interferon-α used in cats with FIV infection can be given parenterally for a maximum of 6 to 7 weeks in high doses (10^5 to 10^6 IU/kg), leading to measurable serum levels. After 6 to 7 weeks, cats develop antibodies against the human interferon-α. If given orally, interferons are destroyed in the gastrointestinal (GI) tract and no measurable serum levels develop. The only potential effect that oral interferon could have is stimulation of the lymphoid tissue in the oral cavity with subsequent systemic immunomodulation. No placebo-controlled studies prove a positive effect of low-dose oral human interferon-α in FIV-infected cats. Interferons are species-specific and feline interferon-ω (recently licensed in some countries) is more effective in feline cells than human interferon. So far only one study has been performed with feline interferon-ω in FIV-infected field cats at 10^6 IU/kg every 24 hours subcutaneously for 5

consecutive days. This study failed to show a significant difference in survival rate, although some clinical improvement was noted.[3] Other trials are needed to assess the efficacy of feline interferon-ω against FIV infection.

171.5.2 Immune Modulatory Therapy

Nonspecific immunostimulatory agents (e.g., Acemannan, *Staphylococcus* protein A (SPA), *Propionibacterium acnes*, paramunity inducer) are probably the most widely used medications in FIV-infected cats. It has been suggested that these agents restore compromised immune function, allowing the patient to control viral burden and recover from associated clinical syndromes. Although reports of uncontrolled studies frequently suggest clinical improvement, these effects have not been observed when followed by controlled studies. No conclusive evidence from controlled studies shows that immunomodulators or alternative drugs have any beneficial effects on health or survival of asymptomatic or symptomatic FIV-infected cats. A nonspecific stimulation of the immune system might even be contraindicated. In HIV-infected people (and in FIV-infected cell cultures), nonspecific stimulation can lead to increased virus replication by activating latently infected lymphocytes and macrophages. Consequently this therapy can actually promote progression of disease. This is why unspecific immunomodulators with unknown effects should not be used in FIV-infected cats.

172 CHAPTER • 172 Feline Infectious Peritonitis and Feline Enteric Coronavirus

Janet E. Foley

172.1 FELINE CORONAVIRUSES

Feline enteric coronavirus (FECV) and feline infectious peritonitis (FIP) virus are two feline coronavirus phenotypes of positive-stranded RNA virus. Like transmissible gastroenteritis virus of pigs, murine hepatitis virus, and others, the FEVC and FIP virus are in the family Coronaviridae. FECV is a fecal-orally transmitted virus that can infect intestinal epithelium of all Felidae but is not infectious to nonfelids or humans. FECV produces moderate villus pathology with no clinically detectable disease; the major clinical importance is that frequent RNA mutations confer a novel phenotype that allows the virus (now an FIP virus) to enter and replicate within feline macrophages.[1,2] If a cat fails to eliminate FIP virus–infected cells early in infection, the presence of FIP virus within macrophages may initiate an ultimately fatal Arthus-type immune-mediated vasculitis, which defines FIP. Affected cats may develop signs due to lesions in a sensitive target organ (central nervous system [CNS], kidney, or liver) or it may die due to fluid redistribution into second spaces, disseminated intravascular coagulopathy, or secondary sepsis.

172.2 DIAGNOSIS OF FELINE INFECTIOUS PERITONITIS

FIP is diagnosed on histopathologic examination of lesions, supported by signalment, history, physical examination, and laboratory findings (Figure 172-1). Cats with FIP may be any breed or either sex, with a peak age distribution from 6 months to 3 years (although FIP occurs in all ages). Commonly, affected cats come from a multiple-cat household (more than five cats), even though the cat may have been in a single-cat household for months or years. Often, cats with FIP have a history of failure to thrive or grow. On physical examination, affected cats may have antibiotic-unresponsive or cycling fever, lethargy, icterus, abdominal masses (especially associated with kidneys, liver, spleen, and mesenteric lymph nodes), and neurologic abnormalities. Diarrhea is not a sign of either FIP or FECV infection. Cats with ocular FIP may have keratic precipitates, anterior uveitis, hypopyon, hyphema, or retinal hemorrhage or detachment. Cats with effusive or “wet” FIP develop a yellow-tinged, high-protein, inflammatory exudate in their abdominal, pleural, pericardial, or scrotal cavities. Pleural effusion may cause dyspnea, and abdominal fluid may cause obvious ascites. Clinical pathologic examination of the fluid indicates either exudate (possibly turbid, specific gravity >1.017, 5 to 12 g/dL protein, moderate numbers of nondegenerate neutrophils, macrophages, plasma cells, and lymphocytes) or occasionally modified transudate. There may be bacteria present, reflecting the cat's immunosuppressed state. Synovial fluid may appear inflamed due to immune complex deposition. Blood testing for coagulopathy may demonstrate increases in prothrombin time (PT) and partial thromboplastin time (PTT) and increased fibrin degradation products.

Several hematologic changes occur in cats with FIP, although many affected cats have patterns differing from “classic.” Cats with FIP often have a mild neutrophilia and lymphopenia. Anemia secondary to red cell destruction or to chronic disease is common. Serum biochemistry results frequently demonstrate increases in serum protein concentration (>8.0 g/dL) consisting of hypergammaglobulinemia. Less commonly, abnormal liver enzyme activities occur due to hepatitis, hepatic lipidosis, or prehepatic sequelae of vasculitis, erythrocyte destruction, and hypoxia. Hyperbilirubinemia is common and secondary to vasculitis within the liver. Affected cats have severe liver disease.

Serology can be helpful as part of the diagnostic profile but is so often misinterpreted that results need to be evaluated carefully. Serology does not differentiate the FIP virus from FECV, is not correlated with severity of

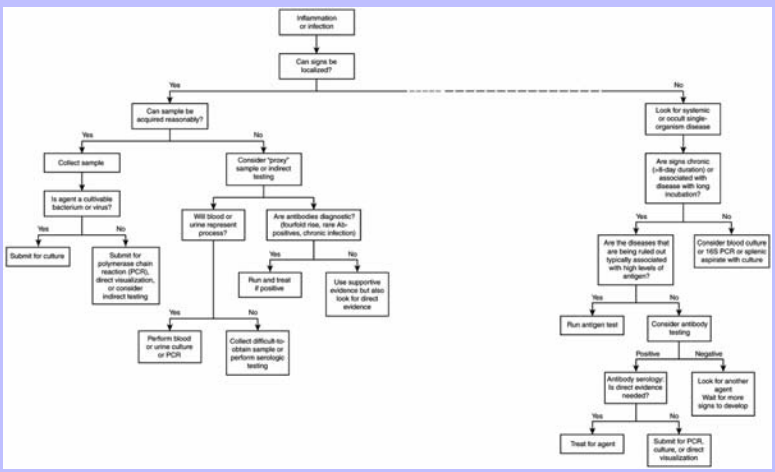
disease, and is not indicative of active infection.[3–6] Most commonly, serology for anti-FECV and FIP virus IgG is an indirect immunofluorescent antibody (IFA) test using FIP virus–infected feline cell lines; enzyme-linked immunosorbent assay (ELISA) is available in some commercial laboratories. Dilution should start at 1:25; if a cat is negative at 1:25, one can assume that the cat is truly negative (or was only exposed within the last 10 days). Unfortunately, many laboratories only report high titers (ε1:400) as positive, despite the fact that FIP can occur in cats with titers lower than 400. Rising titers are not very helpful because cats with FIP and FECV can both have fluctuating titers. Titers greater than 16,000 are suggestive of FIP. In multiple-cat facilities, virtually all cats are seropositive. Kittens in catteries often have high titers (400 to 6400), but most do not develop FIP. Positive titers wane slowly, but cats held in single-cat households with no further exposure to coronavirus eventually become seronegative after months to years if they are not FECV carriers and do not have FIP. Rare cases occur in which cats appear to be seronegative and yet have FIP. In almost all such instances, the problem is with testing: low titers are not detected. Other reported, rare causes of seronegativity in cats with FIP include immune complex consumption of free antibodies, exhaustion of antibody-producing plasma cells, or acute fulminant disease less than 10 days after first exposure to coronavirus. It is technologically possible to generate antibodies to mutant FIP viruses. However, so many potentially different mutations exist that any single antimutant FIP virus antibody becomes useless for routine diagnostic purposes. Commercially available anti-7b antibody tests anecdotally suffer from poor positive and negative predictive values.

Reverse-transcription polymerase chain reaction (RT-PCR) can be performed to reverse-transcribe coronavirus RNA to cDNA and then make visually detectable large quantities of DNA. Although FIP viruses are genetic mutants of FECVs, numerous sites exist in the S, 3c, or 7b genes of FECV that can be mutated or deleted and confer on the virus the capability to infect and replicate within macrophages. Sometimes the change can be a single RNA base. As a result, PCR primers to discriminate between FECV and FIP virus cannot be designed. RT-PCR is sensitive and useful for documenting FECV or FIP virus RNA to confirm that a suspect lesion is due to FIP or that a cat is shedding FECV in feces. All samples for coronavirus PCR must be carefully handled, kept frozen, and protected from RNA-degrading enzymes (which are ubiquitous in most environments). PCR should be performed as quickly as possible after collection, even if samples are frozen; delays in testing may result in false-negative results. In feces, PCR-positive tests document FECV infection. The strength of the PCR signal in feces correlates with the level of infection.[7,8] Because cats with FECV vary in how much FECV is shed in feces, repeated PCR should be performed daily over 4 to 5 days to accurately detect whether a given cat sheds FECV.

663

664

Figure 172-1 Algorithm for inflammation or infection.



Urine and cerebrospinal fluid (CSF) are not recommended for FIP PCR, because these fluids contain low numbers of virus. Ascites may be false negative because of PCR inhibitors. Blood and mesenteric lymph nodes may be false positive for FIP (small amounts of FECV). In other lesions, positive PCR can be interpreted as positive for FIP virus.

Confirmation of FIP is made by histopathology of biopsy or necropsy samples with pyogranulomas, coronavirus antigen, or nucleic acids. Hematoxylin and eosin-stained samples contain localized perivascular mixed inflammation with macrophages, neutrophils, lymphocytes, and plasma cells (or any combination of these). Pyogranulomas may be large and consolidated, sometimes with tissue necrosis, or numerous and small. To confirm coronavirus within the lesions, PCR may be performed or formalin-fixed, paraffin-embedded tissues may be stained with a chromagen-tagged monoclonal antibody such as 5.2D5 against the FIP N protein, then lightly counter stained with hematoxylin and eosin.[9]

664 665

In the less commonly encountered cats with the neurologic form of FIP, several ante-mortem tests have a high probability of successfully ruling in or out a diagnosis of FIP. Clinical signs indicate disease in various parts of the spinal cord, cerebrum, and cerebellum and may include seizures, ataxia, paresis, paralysis, vestibular disease, peripheral neuropathy, hyperesthesia, urinary incontinence, and behavior changes. Cats with neurologic FIP are seropositive in blood and in CSF (and often in anterior chamber fluid), with a ratio of CSF: serum antibodies generally much higher than the ratio of CSF protein: serum total protein. The CSF often appears normal, or there may be mild increases in protein concentration and cell number. CNS inflammation often results in hydrocephalus. On magnetic resonance imaging (MRI), hydrocephalus may be observed, as well as contrast enhancement in ependyma, meninges, and other sites.

665 666

172.3 TREATMENT AND PREVENTION OF FELINE INFECTIOUS PERITONITIS

Virtually every cat with confirmed FIP dies. Some veterinarians prescribe immunomodulators (*Propionobacterium acnes* (immunoregulin), interferon, acemannan) to treat cats with FIP with no documented, controlled evidence of efficacy. Immunosuppressive drugs such as prednisone (4 mg/kg, orally once a day) or cyclophosphamide (2 to 4 mg/kg, orally four times a week) may slow disease progression but do not produce a cure. Cats with FIP should also be treated with broad-spectrum antibiotics and supportive therapy (subcutaneous fluids, rest, good nutrition, lack of stress) for as long as they are comfortable. Once disease signs become debilitating and weight and appetite decline, the owner must be prepared for the reality that their cat is dying.

Unfortunately, preventing FIP is extremely difficult. Three prevention targets will be discussed: (1) preventing FIP in cats that were in contact with cats with FIP, (2) preventing FIP in cats harboring FECV, and (3) preventing FECV. After a cat in a household develops FIP, one can do virtually nothing to prevent FIP in other in-contact cats. All cats will have already been exposed to the same coronaviruses, although this is usually an FECV. Few healthy cats in the household will develop FIP, although the stress of being locked in a bathroom in the misguided attempt to prevent exposure would not help remaining cats fight infection. After a diagnosis of FIP, the probability of any other cat dying of FIP is no higher than in any other cattery with endemic FECV (which is all catteries). Exceptions exist to this rule. The first is full-sib littermates of cats with FIP, which have a 0.25 to 0.5 probability of dying of FIP as well. The second exception is during rare epidemics that may be associated with spread of FIP (in contrast to the typical scenario of spread of FECV and periodic mutations to FIP virus).[3] This type of spread of FIP virus has not been documented in natural epidemics and is unlikely, because FIP lesions are not in epithelial surfaces where the virus could be shed.

The second target is to prevent FIP in catteries with endemic FECV. This includes virtually all multiple-cat households, breeding catteries, shelters, foster homes, and other homes with more than five cats. Various tactics have been used. To be successful, they should focus on supporting cats' natural resistance to FIP virus phenotypes and reducing FECV challenge in these cats. In catteries, the major risk factor for FIP is the overall prevalence of FECV. Reducing the number of cats (especially kittens less than 12 months old) and keeping possibly FECV-contaminated surfaces clean can minimize population loads of FECV.

Vaccination is supposed to help cats fight FIP but has not proven to do so. Often cats do not seroconvert after vaccination, and study results are mixed as to whether vaccination has no effect versus a small effect. Although marginally if at all efficacious, the vaccine is safe and does not induce antibody-dependent enhanced FIP.

It is reasonable in breeding catteries to maximize heritable resistance to FIP. If a cat has two or more litters that develop FIP (at any age), then that cat should not be bred again. It would be rare for such a cat to have FIP, so it should be screened (complete blood count [CBC], serology, abdominal palpation, and possibly ultrasound). If no abnormalities are found, the animal should be neutered and placed for adoption. Particular attention should be paid to pedigrees of toms where FIP is over-represented. Because line breeding often uses valuable toms extensively, eliminating such toms may have a small but important effect on improving overall resistance.

Concurrently with palliative efforts, cattery managers should use education and communication to minimize adverse effects of FIP on cat populations. For example, if a shelter has a reputation for having FIP, adoptions may be reduced and cats may be euthanized for space. Cattery managers should have written information sheets or contracts informing buyers or adopters about FECV and FIP. They should understand that FECV is unavoidable in multiple-cat environments and that FIP is an unavoidable consequence of endemic FECV. It is particularly important that cats associated with the cattery be diagnosed accurately. For example, cats from shelters may have moderately high FECV titers *not* due to FIP and yet be euthanized inappropriately because of a history of having been at a shelter.

The last FIP-prevention scenario is to prevent or eliminate FECV, which is difficult. Isolation is not effective because of the ease with which FECV is transported on things such as clothes, shoes, dust, and cats' fur. As long as five or more cats live in a home, FECV infection maintains itself by infecting and reinfecting the same cats, whether or not the cats are separated. When the number of cats drops to five or fewer, it is much more difficult for the virus to sustain itself.

If depopulation is possible, a chance exists that endemic FECV can be induced to become extinct in the cat population. It is important to determine whether any cats are chronic FECV carriers so that they can be removed. Forty to 60% of cats in large multiple cat environments shed virus in their feces at any given time. About 20% will shed virus persistently, whereas 20% will be immune and not shed virus. Repeated PCR testing of feces should be performed at weekly intervals for 2 months or more to document carriers: if the cats remain persistently PCR-positive more than 6 weeks, they should be placed for adoption (only in very small catteries attempting to eradicate FECV).

Early weaning has been proposed as a means to interrupt transmission from adult cats to kittens. Unfortunately, queens may infect kittens as early as 5 to 6 weeks. This is prohibitively young to be removing kittens from the nurturing of the queen, particularly when the kittens likely will be exposed within a few weeks anyway. For early weaning to be effective, kittens should be taken to a new home (with no other cats) at 5 weeks of age. Even then, early weaning is not always successful.

To conclude, management of FIP should be directed at minimizing the population impact and accurately diagnosing and supporting individually affected cats. Vaccination neither prevents FIP nor FECV; testing and

removing is ineffective. Thus cattery managers have few effective management tools. However, veterinarians need to be knowledgeable regarding both successful and unsuccessful strategies to provide useful counsel to their clients with multiple-cat households.

173 CHAPTER • 173 Other Feline Virus Diseases

Rosalind M. Gaskell

Susan Dawson

173.1 FELINE VIRAL RESPIRATORY DISEASE

Feline viral respiratory disease (Table 173-1) is most commonly seen where cats are grouped together, such as in breeding and boarding catteries and in rescue shelters. The two main causes of viral respiratory disease in cats are (1) feline herpesvirus 1 (FHV-1) (feline rhinotracheitis virus) and (2) feline calicivirus (FCV). FHV-1 generally induces a more severe disease than FCV, but FCV appears to be relatively more common.[1] Other viruses implicated in the syndrome include feline reovirus and cowpox virus (see following). Bacterial pathogens such as *Bordetella bronchiseptica* and *Chlamydophila felis* may also be involved in infectious respiratory disease in cats.

173.1.1 Causative Agents

FHV-1 is an alphaherpesvirus affecting both domestic cats and other members of the Felidae. Only one serotype of the virus exists, and genetically all isolates are very similar. The virus contains double-stranded DNA and is enveloped, making it relatively labile.

FCV is a small nonenveloped RNA virus. Only one genotype and one serotype of the virus exist, although a large degree of variability exists within both of these.[2,3] However, most strains of FCV are closely related enough antigenically to induce some degree of cross-protection, and this has been used in developing vaccines.

FCV affects both domestic cats and some nondomestic Felidae. Although dogs have their own genetically distinct calicivirus, some canine calicivirus isolates appear to be closely related to FCV and some epidemiologic evidence indicates of a link between the two.[4,5]

FCV is slightly more resistant than FHV-1 and is less susceptible to some disinfectants. However, a diluted hypochlorite and detergent mixture should be effective for both viruses.

173.1.2 Clinical Signs

FHV-1 causes upper respiratory tract (URT) disease, with oculonasal discharges, conjunctivitis, sneezing, and sometimes hypersalivation and coughing. Occasionally more severe signs including pneumonia and generalized disease may be seen, particularly in young or debilitated animals. Abortion occurs rarely and is probably due to severe systemic disease rather than a direct effect of the virus itself. The role of FHV-1 in ocular disease has been increasingly recognized, with keratitis, corneal sequestration and a possible association with uveitis having been reported.[6] Similarly, involvement of FHV-1 with skin ulcers and dermatitis has also been described.

FCV causes typical URT signs, but the disease is generally milder than that seen with FHV-1. Mouth ulceration is a characteristic feature of the disease, typically on the tongue, but lesions may occur elsewhere in the mouth or on the skin. Lameness and pyrexia may also occur, with or without respiratory or oral disease. In addition, FCV infection is associated with chronic stomatitis, although its precise role in the condition is not clear and other factors are likely to be involved.[1]

There is some strain variation in FCV with respect to pathogenic potential. Some isolates appear to be apathogenic, some may induce an interstitial pneumonia, and more recently very virulent strains have emerged in California that induce a hemorrhagic syndrome. Affected cats had variable signs, such as facial and paw edema, respiratory signs, pyrexia, icterus, and hemorrhages from the nose and in the feces.[7]

173.1.3 Diagnosis

Diagnosis of FHV-1 and FCV infection has classically been confirmed by virus isolation in cell culture from oropharyngeal or conjunctival swabs, although immunofluorescence has also been used (particularly for FHV-1). Increasingly, polymerase chain reaction (PCR) is being used for diagnosis of FHV-1, because it is significantly more sensitive than traditional methods.[8,9] However, the clinical and epidemiologic significance of PCR-positive and virus isolation–negative cats is currently unclear. For FCV, reverse-transcriptase polymerase chain reaction (RT-PCR) is less sensitive than isolation but it is useful for differentiating between strains in investigating the epidemiology of the disease.[10]

173.1.4 Treatment

Treatment involves both broad-spectrum antibacterial cover and supportive therapy. Tetracyclines are indicated if *Bordetella bronchiseptica* or *Chlamydophila felis* are involved. No specific antivirals are licensed for use in either FHV-1 or FCV infection. Some antiherpesvirus drugs used in human medicine, such as acyclovir, are not sufficiently active against FHV-1 or are too toxic for use in cats.[11] However, others have been used with some success in cats with ocular herpesvirus lesions.[12] For FCV, ribivarin has been shown to be effective in cell culture but was too toxic for use in cats. It has been suggested that recombinant interferon may be helpful in cats with viral respiratory or ocular disease.[12] In addition, some evidence reveals that orally administered L-lysine may be useful in treating acutely and latently FHV-1 infected cats.[13]

173.1.5 Epidemiology

Both viruses are primarily transmitted by direct contact between cats, although indirect transmission may also occur in the short term through contact with infectious discharges. Aerosols are not of major importance, although sneezed macrodroplets may transmit infection over a distance of 1 to 2 m.

Acutely infected cats are clearly an important source of virus, but infection also commonly occurs from clinically recovered carrier cats. In FHV-1 carriers, the virus persists in a latent form largely in trigeminal ganglia, although other tissues may also be involved. Periodically, particularly after a stress, virus reactivates in such carriers, and they can then infect other animals. Stresses that may induce virus shedding include a change of housing, kittening and lactation, and corticosteroid treatment. Some cats may show clinical signs during a reactivation episode, which can be a useful indicator that they are likely to be infectious.

Table • 173-1 Recognized Virus Infections of Cats

Upper Respiratory Tract (URT) Viruses	Feline herpesvirus type 1 (FHV-1)	URT disease
	Feline calicivirus (FCV)	URT and oral disease; sometimes lameness
	Feline reovirus	Conjunctivitis/respiratory lesions/diarrhea, experimentally; no evidence important in the field
Enteric Viruses	Feline parvovirus (FPV)	Enteritis and panleukopenia; cerebellar hypoplasia; fetal death
	Feline coronavirus	Mild enteritis; feline infectious peritonitis (FIP)
	Feline rotavirus	Mild diarrhea; disease uncommon
	Feline astrovirus	Persistent watery diarrhea; disease uncommon
	Feline torovirus	Putative torovirus detected in cats; possible association with protruding nictitating membrane and diarrhea syndrome in cats
Retroviruses	Feline leukemia virus (FeLV)	See Chapter 170
	Feline immunodeficiency virus (FIV)	See Chapter 170
	Feline foamy virus (FFV)	Previously feline syncytium-forming virus; no definite disease association
Miscellaneous Virus Infectious of Cats	Cowpox virus	Sporadic disease in cats; mainly skin lesions; cowpox virus endemic in small wild rodents
	Hantavirus	Endemic disease in rodents; serologic evidence of infection in cats; zoonotic (but cats are unlikely source)
	Rabies virus	See Chapter 177
	Aujeszky's disease virus/pseudorabies virus	Herpesvirus infection in pigs/swine; cats occasional host; disease signs are severe behavioral changes, pruritus, paralysis, coma, and death
	Feline herpesvirus type 2 (FHV-2)	Possible association with idiopathic feline lower urinary tract disease, now thought to be bovine herpesvirus 4; possible disease association unclear
	Canine distemper virus (CDV)	Evidence from field serology and experimental studies indicate that cats can be infected subclinically; however, severe disease with neurologic signs seen in large Felids
	Paramyxoviruses: hendra and nipah viruses	Newly emerged, fatal zoonotic respiratory disease of horses in Australia (Hendra virus) and pigs in Malaysia (Nipah virus); endemic in certain species of fruit bats; cats can be infected experimentally with both viruses
	Paramyxovirus: unclassified	Report of demyelinating lesions in central nervous system (CNS) of cats
	Influenza virus	Can replicate in cats after experimental inoculation but no disease signs; no evidence of cat-human transmission; may occur in reverse during human influenza outbreaks
	Borna disease virus (BDV)	Rare but fatal neurologic disease that occasionally occurs in cats
	Arthropod-borne viral infections	Cats in some parts of the world may become infected with several arthropod-borne diseases; usually asymptomatic, occasionally cause encephalitis

Unlike FHV-1 carriers, FCV carriers shed virus more or less continuously and are therefore always infectious to other cats. The virus persists in tonsil and other oropharyngeal tissues. In some cats the carrier state appears to

be lifelong, but most spontaneously recover at some point and appear to eliminate virus. FCV carriers appear to be very common, with approximately 20% to 30% of cats in the general population shedding FCV.[1]

173.1.6 Prevention and Control

Prevention and control may be achieved through a combination of vaccination and management. Both modified-live virus (MLV) vaccines and inactivated adjuvanted vaccines are marketed for parenteral injection against FHV-1 and FCV. Modified-live intranasal vaccines are also available in some countries but are not widely used. A number of recombinant vaccines have also been created, including FHV-1 deletion mutants, baculovirus constructs, a myxoma FCV recombinant, and an FCV DNA vaccine.

668

669

Both MLV and inactivated FHV-1 and FCV vaccines are reasonably effective at protecting against disease, but none protects against infection or the development of the carrier state. For FCV, various strains are used in commercial vaccines, for example, strains F9 and 255. Most seem to protect against the majority of FCV isolates but not as well against all of them. Some evidence suggests that the percentage of isolates neutralized by such strains is decreasing.

Parenteral MLV vaccines are generally safe, but disease signs may occasionally occur after their use. This may be due to inadvertent oronasal exposure to the vaccine, for example, if the cat licks the injection site, and occasionally vaccine virus may generalize and spread.[10,14,15] Inactivated adjuvanted vaccines may therefore be safer in disease-free colonies. However, adjuvants can sometimes cause local or systemic reactions, and (very rarely) sarcomas may develop at the site of injection.

Intranasal MLV vaccines induce better protection but often at the expense of slight side effects, such as sneezing and oculonasal discharges. They are however useful for rapid onset of protection.

Primary vaccination in young kittens is generally at 8 to 9 weeks of age, with a second dose at 12 weeks. Boosters are traditionally recommended every year, but immunity may last longer in some cases.[16] In view of this and because of concerns over vaccine site reactions, it has been suggested that after the first annual booster, revaccination intervals may be extended to up to 3 years.[17] However, an individual risk-benefit assessment should be carried out to determine the most appropriate vaccination strategy for a particular animal[18] (see Chapter 164).

Management measures are aimed at preventing spread of viruses within a cattery, through both direct and indirect contact between cats. In boarding catteries and rescue shelters, cats should be individually housed with solid partitions between pens, and good hygiene and disinfection procedures should be used. In breeding colonies, young kittens are most at risk when they lose their maternally derived antibodies (MDA). Overcrowding should be avoided and cats kept as stress free as possible. Ideally, queens should kitten in isolation with early weaning of kittens or earlier vaccination schedules implemented if required. Such measures have been described in detail elsewhere.[1]

173.2 FELINE PANLEUKOPENIA/FELINE PARVOVIRUS (FPV) INFECTION

Feline panleukopenia is a highly infectious disease affecting members of the Felidae and a number of other species including mink, ferrets, and raccoons. The disease is characterized by enteritis and a panleukopenia and has a high mortality. Vaccination is generally highly effective in controlling the disease.

Feline panleukopenia is caused by a parvovirus, a small nonenveloped DNA virus similar to the canine parvovirus type 2 (CPV-2), which causes a severe hemorrhagic enteritis in dogs. Although feline panleukopenia is a long-established disease of cats, CPV-2 emerged suddenly in 1978 as a host range variant of FPV and spread rapidly within the dog population. The mechanism of its evolution is unknown, but it has been suggested that it may have originated from a wild carnivore intermediate host.[19] CPV-2 has largely been replaced by CPV-2a and CPV-2b, which now coexist in dog populations worldwide.[20] Although CPV-2 isolates did not replicate in cats, both CPV-2a and CPV-2b do so and have been reported to constitute a small proportion of isolates found naturally in cats.[21–23] In addition, some evidence suggests that the percentage of CPV isolates from cats in some parts of the world is increasing and that a potential new variant, CPV-2c, from leopards may also have emerged.[22]

Parvoviruses have an affinity and requirement for actively dividing cells. The main target tissues are the rapidly dividing cells of lymphoid tissue and the bone marrow, leading to panleukopenia, and the crypt epithelium of the intestinal mucosa, leading to enteritis. Infection early in pregnancy may lead to fetal death and resorption. From the middle third of gestation to immediately postnatally, infection results in cerebellar hypoplasia in kittens.

The severity of the disease varies considerably, ranging from a subclinical infection to a peracute syndrome with sudden death. In general, the disease appears to be more severe in young kittens. Other factors, such as a change of food or coinfection with other pathogens, which increase the mitotic rate in the intestinal villi, may increase the severity of disease. In a typical case the first signs of illness are lethargy, fever, and anorexia with apparent thirst but refusal to drink. Affected cats may vomit, particularly in the early stages. Profuse watery diarrhea or dysentery then develops, and cats may become severely dehydrated. Most fatalities occur within 3 to 5 days of the first signs of illness and are probably due to overwhelming bacterial infection, dehydration, and electrolyte imbalance. Experimental infections have suggested that infection with CPV in cats may lead to milder disease with reduced virus shedding compared with FPV, although the situation in the field is unclear.[24,25]

Kittens with cerebellar hypoplasia show ataxia, incoordination, hypermetria, and often intention tremors. These signs persist for life. Nevertheless, affected kittens may learn to compensate and otherwise function normally. Forebrain lesions have been reported and may lead to seizures and behavioral abnormalities.[26] Retinal lesions may also be present but are usually of no clinical significance. A possible role of FPV in myocarditis and idiopathic cardiomyopathy has also been suggested.[27]

A presumptive diagnosis of feline panleukopenia may be made based on history, vaccination status, and clinical signs. Disease is more commonly seen in rescue shelters and in groups of unvaccinated cats. Virus culture from fecal samples is difficult, and fecal shedding only occurs for a short period after infection. Enzyme-linked immunosorbent assays (ELISAs) and rapid immunomigration tests have been used for detection of viral antigen in fecal samples, with variable sensitivity and specificity. More recently, PCR tests for the detection of viral DNA in fecal samples have been used, and these have good sensitivity.[28] Antibody levels, which may reach very high titers after an active infection, may be useful as an aid to diagnosis.

Diagnosis may also be confirmed at necropsy, where characteristic histopathologic changes, including the presence of intranuclear inclusion bodies, may be seen in the crypt epithelium of the small intestine. Specific diagnosis using in situ hybridization and immunohistochemistry has also been reported.

Treatment is largely supportive and is aimed at restoring the fluid and electrolyte imbalance and covering against secondary bacterial infection.

Both MLVs and inactivated parenteral vaccines are available. Only one serotype of the virus exists, and the vaccines are generally highly effective in preventing disease. Protection against CPV-2b has also been shown experimentally,[24] and it is likely that FPV vaccines will protect against such isolates in the field. Primary vaccination usually takes place at 8 to 9 weeks of age, with a second dose at 12 weeks. However, the duration of MDA in kittens can be quite variable, and those born to unvaccinated queens or those who have not suckled colostrum may have no or very low levels of MDA. In contrast, kittens born to recovered queens may have very high levels of MDA lasting up to 20 weeks. MLV vaccines should not be used in kittens under 4 weeks of age or in pregnant queens because of the risk of the development of cerebellar hypoplasia.

669

670

Boosters have typically been administered every 1 to 2 years, although some evidence suggests that immunity may last longer.[16] Consequently, and because of possible safety issues with respect to feline vaccines, three yearly intervals are now being suggested by some.[17]

Although the disease has largely been controlled by vaccination, cases still occur, particularly in rescue shelters and sometimes also in breeding colonies.[29] FPV is a remarkably stable virus and may persist in infected premises for up to 1 year: subclinical infection of susceptible cats can also help maintain the virus within a population. Not all disinfectants are active against FPV, but sodium hypochlorite and glutaraldehyde solutions are effective. Because of the ability of the virus to survive in the environment, thorough disinfection of premises must be carried out after any disease outbreaks and any new cats admitted to such infected premises should be fully vaccinated. Although persistent infections may occasionally occur after in utero or neonatal infection, carriers do not play a significant role in the epidemiology of the disease.

173.3 BORNAVIRUS DISEASE (FELINE "STAGGERING DISEASE")

Borna disease (BD) is a rare but fatal neurologic disease caused by a negative-stranded RNA virus, Borna disease virus (BDV). The disease occurs predominantly in horses and sheep; but a number of other species may also be affected, and increasing evidence indicates that cats are also susceptible.[30,31] The disease in cats has been reported mainly in Europe but also occurs in other parts of the world, including Japan.[32] Affected cats show motor dysfunction and behavioral changes including an unsteady "staggering" gait, depression, and progressive hindlimb ataxia and paresis. Other signs include anorexia, increased salivation, hyperesthesia, impaired vision, and seizures. The disease is generally progressive; despite supportive treatment, affected cats die or are euthanized. At necropsy a characteristic nonsuppurative meningoencephalomyelitis is seen mainly in the gray matter of the cortex, brain stem, and spinal cord. In some cases, evidence of BDV infection is seen in cats with no neurologic disease. It has been suggested that BDV or a related virus may be involved in psychiatric disorders in humans.[33]

173.4 POXVIRUS INFECTION

Cats are susceptible to cowpox virus, a member of the Orthopoxvirus family.[34,35] Occasional cases of parapoxvirus infection in cats have also been reported.[36] Cowpox virus is found only in Eurasia, and the reservoir hosts are small wild mammals such as voles and woodmice. The disease is mostly seen in rural cats that hunt rodents, and most cases are seen in summer and autumn when opportunities for contact with the reservoir hosts are highest. Cat-to-cat transmission rarely occurs and generally causes only subclinical infection.

The disease typically starts with a single primary lesion, generally on the head, neck, or forelimb, which may be ulcerated or scabbed and can become secondarily infected. Although some cats may only have a primary lesion, in

many cases widespread secondary skin lesions also develop after 1 to 3 weeks. These appear as randomly distributed, small epidermal nodules that increase in size over a few days to well-circumscribed ulcers about 1 cm diameter. These gradually become scabbed and heal over a period of 4 to 5 weeks, and most animals recover uneventfully. Occasionally, especially in immunosuppressed cats, systemic illness may develop. Some exotic felids (e.g., cheetahs) are particularly susceptible, and a rapidly fatal pneumonia often develops.

Diagnosis is by virus culture, electron microscopy (EM), or PCR of scab material, or by serology.[37,38] Characteristic histopathologic lesions include the presence of intracytoplasmic, eosinophilic inclusion bodies. Immunostaining is a useful aid to diagnosis.

Treatment includes broad-spectrum antibiotics to control secondary bacterial infection and general supportive therapy with fluids where necessary. Glucocorticoids are contraindicated because they can predispose to the development of secondary lesions, more severe disease, or both. Cidofovir has been shown to be active against cowpox virus in cell culture and some animal systems, although its use in cats has not been reported.[39] No vaccines are available, although vaccinia (smallpox vaccine) may be considered for valuable zoo collections.[40] Cowpox is zoonotic and may cause both a localized lesion and sometimes severe systemic illness in infected people, particularly those who are immunosuppressed. However, the risk of cat-human transmission is small if basic hygiene precautions are taken.

173.5 FELINE FOAMY VIRUS (FELINE SYNCITIUM-FORMING VIRUS) INFECTION

Feline foamy virus (FFV) is a member of the foamy virus group (spumaviruses) in the retrovirus family. Spumaviruses have been isolated from many species, but they generally do not appear to be pathogenic. Their main importance lies not in clinical medicine but as potential contaminants in research and vaccine production and, more recently, as possible viral vectors in recombinant vaccine technology.

FFV infection is very common in cats, with seroprevalences of up to 90%, depending on the population tested.[35,41] Infected cats harbor virus indefinitely; therefore seropositivity equates with infection. FFV is transmitted horizontally, and in some cases vertically, from infected queens to kittens.

The virus has been isolated from both clinically healthy cats and cats with a variety of diseases, although no clinical signs have been seen after experimental infection. However, FFV may predispose to disease in conjunction with other agents or particular MHC types. Such an association has been suggested for FFV in the feline progressive polyarthritis syndrome.[42]

173.6 ASTROVIRUS

Astroviruses have been detected in a number of species including cats, and in humans are a common cause of gastroenteritis. Astroviruses have been detected in the feces of kittens with diarrhea, and in normal cats.[43,44] The diarrhea has been described as persistent (4 to 14 days) and watery and may be accompanied by vomiting, pyrexia and depression. Mild diarrhea has also been reproduced experimentally.[43] It is not clear how commonly astrovirus-induced disease occurs in cats: a limited serologic study has reported that less than 10% of cats in the UK have antibody, although this may be an underestimate as only one serotype was examined.[45]

Serologic cross-reactivity has been reported between feline astrovirus and human sera and a close phylogenetic relationship shown between pig, human, and feline astroviruses. However, no evidence indicates on-going human-animal transmission, although it may have occurred in the past.

173.7 FELINE REOVIRUS INFECTION

Reoviruses have been isolated from both healthy and diseased cats with a variety of signs. Serologic surveys suggest infection is widespread, although the clinical importance of reovirus infection in cats is unknown.[35] Three serotypes of the virus exist. Experimental inoculation of kittens with serotype 3 induced predominantly conjunctivitis, photophobia, and serous ocular discharges; type 2 induced mild diarrhea[46]; and newborn kittens inoculated with type 1 nursed poorly and died 2 days later with respiratory lesions identified at necropsy.[35,47] However, little evidence suggests that these conditions occur in the field.

670 671

173.8 ROTAVIRUS

Rotaviruses are a major cause of enteritis in humans and in many animal species such as cattle and pigs. Typically rotavirus infections occur in neonatal animals, although older animals may also be affected.

In cats, rotavirus infection is widespread, with between 28% to 100% of cats seropositive depending on the population sampled.[35,48] However, clinical disease appears to be uncommon, and diarrhea, when it occurs, tends to be mild and of only short duration.[35,49,50] Diagnosis of rotavirus infection may be carried out from fecal samples by EM, polyacrylamide gel electrophoresis of viral RNA, or by PCR.[45] Because of serologic differences between strains, ELISAs developed for diagnosis of human rotavirus infections may not necessarily detect all feline rotaviruses.[45]

Cross-species transmission is known to occur with rotaviruses experimentally, although to what extent this happens under natural conditions is not known. A number of recent reports have shown close phylogenetic relationships between some feline and some human rotavirus strains, and it has been suggested that cross-infection between cats and humans may sometimes occur.

173.9 HANTAVIRUS INFECTION

Hantaviruses are enzootic worldwide in wild and laboratory rodents, and they are zoonotic.[51] However, strains vary in their pathogenicity to humans. Disease syndromes seen in humans include hemorrhagic fever with renal syndrome in Asia and hantavirus pulmonary syndrome in North America. Only mild or subclinical disease is seen with most European strains.[52]

Hantavirus antibody has been detected in laboratory-housed cats in Belgium and in up to 10% cats from a variety of backgrounds in the United Kingdom, Austria, and Canada.[53–55] In addition, virus has been isolated from a cat in China.[56] However, the clinical significance of Hantavirus infection in cats is not known. There is little evidence to suggest that in most parts of the world cats are likely sources of human infection; however, an increased risk of human infection associated with cat ownership has been reported in China.

173.10 TOROVIRUS INFECTION

Toroviruses are a group of viruses similar to coronaviruses, but with a characteristic rod-or doughnut-shaped core. They have been detected in a number of species including cattle (Breda virus), horses (Berne virus), and humans and tend to be associated with enteritis. There is some evidence for a torovirus of cats that may be associated with

protruding nictitating membrane and diarrhea syndrome.[48] However, other workers have been unable to substantiate this.[57]

174 CHAPTER • 174 Systemic Mycoses

Joseph Taboada

Amy M. Grooters

Systemic mycoses are fungal infections that disseminate from a single portal of entry. The respiratory system serves as the portal of entry for most systemic fungi that affect the dog and cat, but the gastrointestinal (GI) system is occasionally implicated.[1]

Systemic mycoses are becoming more worrisome in human medicine because of immune-suppressive diseases such as acquired immunodeficiency syndrome (AIDS) and the expanded use of immune-suppressive therapy for cancer and organ transplantation. Immune suppression does not play as important a role in veterinary patients, but the importance of such diseases in humans has led to tremendous pharmacologic advances in the treatment of fungal infections.

Systemic fungal infections cause disease, the clinical signs of which are dependent on which systems are involved (Table 174-1). Weight loss, lymphadenopathy, and fever are typical of most systemic mycoses. Because the respiratory system is the usual portal of entry, clinical signs such as cough, dyspnea, and exercise intolerance are common. If the GI system is the portal of entry, as may occur with histoplasmosis, malabsorption may lead to severe diarrhea and weight loss.

In most cases, diagnosis of a systemic mycosis is dependent on demonstrating the presence of the organism in tissue. For yeasts such as *Cryptococcus* or *Candida,* or for dimorphic fungi that have a yeast phase in tissue, such as *Blastomyces dermatitidis* or *Histoplasma capsulatum*, the diagnosis can usually be made cytologically. For other fungi that grow as hyphal organisms in infected tissue, the diagnosis is usually dependent on histopathology, culture, or molecular techniques. Serology is used extensively in practice to support the diagnosis of fungal infections, but with the exception of tests for cryptococcal antigen, most commercially available assays determine the presence of antibody and may indicate only previous exposure.

Many treatment regimens have been reported for the management of various systemic mycoses, but few veterinary studies have been performed that have critically evaluated these agents in a prospective manner, and studies comparing treatment regimens are practically nonexistent. A lack of controlled observations has led to recommendations that are based primarily on anecdotal information, extrapolation from what is done in people, and small retrospective studies. The “best” treatment regimen for any given systemic fungal infection is therefore largely a matter of opinion.

Table • 174-1 Differential Diagnoses for Systemic Manifestations of Systemic Mycoses

Multisystemic granulomatous, neoplastic, and immune-mediated diseases must be differentiated from disseminated systemic mycoses.

Differential Diagnosis for Nodular Skin Disease

Bacterial skin disease

Actinomycosis
Mycobacteriosis
Botryomycosis
Brucellosis
Rhodococcus equi infection
Bartonella vinsonii Subs, *berkhoffi infection*

Mycotic and miscellaneous infectious skin disease

Cryptococcosis
Coccidioidomycosis
Sporotrichosis
Basidiobolomycosis
Conidiobolomycosis
Phaeohyphomycosis
Hyalohyphomycosis
Eumycotic mycetoma
Dermatophytic mycetoma
Protothecosis
Pythiosis
Lagenidiosis
Nodular leishmaniasis

Noninfectious pyogranulomatous skin disease

Foreign body reaction
Idiopathic nodular panniculitis
Sebaceous adenitis (nodular form)
Canine cutaneous sterile pyogranuloma/granuloma syndrome

Neoplasia

Squamous cell carcinoma
Cutaneous lymphoma
Mycosis fungoides (cutaneous T-cell lymphoma)
Cutaneous histiocytosis

Miscellaneous diseases

Systemic lupus erythematosus (SLE)
Systemic vasculitis
Cutaneous embolic disease

Differential Diagnosis for Chorioretinitis, Exudative Retinal Detachment, and Panophthalmitis

Fungal

Cryptococcosis
Coccidioidomycosis
Geotrichosis
Histoplasmosis
Aspergillosis

Neoplasia

Lymphosarcoma
Metastatic neoplasia

Miscellaneous infectious causes

Protothecosis
Brucellosis

Toxoplasmosis *Neosporum caninum* infection Leishmaniasis Lymphadenopathy must be differentiated from numerous causes, including lymphosarcoma, other fungal infections, rickettsial diseases, brucellosis, mycobacteriosis, protothecosis, and leishmaniasis. Solitary bone lesions must be differentiated from primary or metastatic bony neoplasia and other fungal or bacterial osteomyelitis.

The principal antifungal agents are antibiotics produced by microorganisms (e.g., amphotericin B, griseofulvin) and synthetic agents (e.g., potassium iodide, flucytosine, azole derivatives, allylamine derivatives, chitin synthesis inhibitors). The options for treatment of fungal infections increased substantially during the 1990s with the Food and Drug Administration's approval of the azole derivatives fluconazole and itraconazole. Clinical trials have been performed using itraconazole,[2–4] and case reports and retrospective reviews documenting the use of both drugs are available in the veterinary literature. The high cost of most antifungal agents and the long treatment protocols required affect the number of cases that are treated, both limiting and probably epidemiologically biasing the data that have been generated to date. Adding to the difficulty of assessing the efficacy of antifungal agents are that the pharmacologic principles of antifungal therapy are only partially understood, in vitro testing of fungi for resistance to antifungal agents provides little clinically useful information, susceptibility testing yields variable results, and tissue distribution of antifungal agents correlates variably with the clinical outcome.

174.1 ANTIFUNGAL AGENTS

174.1.1 Amphotericin B

Amphotericin B is a polyene macrolide antibiotic produced by the aerobic actinomycete *Streptomyces nodosus*. It was discovered in the 1950s and was one of the first antifungal agents found to be widely useful in treating systemic fungal infections. It has become the gold standard against which the efficacy of new antifungal agents is compared; despite significant toxicity and poor oral bioavailability, it remains the drug of choice for the treatment of many invasive mycoses. The traditional formulation of amphotericin B is a desoxycholate preparation (Fungizone) that, after intravenous administration, is highly protein bound (91% to 95%), primarily to lipoproteins, erythrocytes, and cholesterol in the plasma, and then is redistributed from the blood to the tissues. Penetration into the cerebrospinal fluid (CSF) is poor. Tissue accumulation accounts for the majority of drug disposition. Only 5% to 10% of amphotericin B is excreted in the urine and bile. Although great care should be used when treating animals in renal or hepatic failure, no modification of the dose is necessary unless the renal or hepatic damage is attributable to the drug. Amphotericin B acts by binding to sterols in cell membranes, especially ergosterol in fungal cell membranes. Binding alters membrane permeability, causing leakage of sodium, potassium, and hydrogen ions and eventually leading to cell death. Amphotericin B probably also has important immunostimulatory effects by oxidation-dependent stimulation of host macrophages.[5] Stimulation of macrophages may play an important role in the treatment of some systemic fungal infections with amphotericin B. Toxic effects are attributable to affinity for sterols such as cholesterol in mammalian cell membranes.

672
673

Amphotericin B has been effective in the treatment of blastomycosis, histoplasmosis, coccidioidomycosis, cryptococcosis, systemic candidiasis, zygomycosis, and occasionally pythiosis. It is administered as a series of intravenous infusions (0.22 to 0.5 mg/lb [0.5 to 1 mg/kg] every 48 hours to a cumulative dose of 2 to 4 mg/lb [4 to 8 mg/kg] or until azotemia occurs). Bolus dosing over 5 to 10 minutes is common, but clinicians can reduce renal toxicity by infusing the drug in 5% dextrose over 1 to 5 hours. Nephrotoxicity is the most signi-ficant adverse effect and is dose dependent.[6] Generally, renal azotemia is reversible, and renal function returns to

normal after cessation of therapy. However, return to pretreatment values may take several months. Irreversible renal dysfunction is more likely in animals with pre-existing azotemia or in those receiving other nephrotoxic agents such as aminoglycosides. Blood urea nitrogen (BUN) should be monitored before each administration of amphotericin B. If the BUN is greater than 50 mg/dL, the drug should be discontinued until the azotemia has resolved. Clinicians believe nephrotoxicity is caused by disruption of renal tubular epithelial cell permea-bility resulting in increased delivery of chloride ions to the distal tubule, with subsequent decreased glomerular filtration rate (GFR) being the result of tubuloglomerular feedback. This feedback is amplified by sodium depletion and suppressed by sodium loading. Administration of 0.9% sodium chloride (5 to 10 mL/lb) before amphotericin B administration decreases the incidence of nephrotoxicity in people. Other possible mechanisms of nephrotoxicity include decreased renal blood flow and direct renal cellular toxicity. Tumor necrosis factor (TNF) may also play a role in mediating amphotericin B–induced azotemia. Pentoxifylline, a hemorrheologic drug, seems to exert protective effects in people and rats. Mannitol and dopamine have also been shown to decrease nephrotoxicity in experimental situations. Other possible toxic effects include thrombophlebitis, pyrexia (usually ameliorated by pretreatment with nonsteroidal anti-inflammatory drugs or anti-inflammatory doses of glucocorticoids), hypokalemia, distal renal tubular acidosis, hypomagnesemia, cardiac arrhythmias, and nonregenerative anemia. Calcinosis cutis has been reported in dogs with blastomycosis 2 to 4 weeks after beginning treatment with amphotericin B.[7]

Recently the use of novel delivery systems have been effective in reducing nephrotoxicity and improving site-specific delivery of amphotericin B, allowing higher doses to be administered. Currently three new formulations of amphotericin B are available for clinical use in human patients: (1) amphotericin B lipid complex (ABLC) (Abelcet®, Enzon), (2) amphotericin B colloidal dispersion (Amphotec®, Intermune, Inc.), and (3) liposome-encapsulated amphotericin B (AmBisome®, Gilead Sciences).[8] Of these three formulations, ABLC has been the most extensively evaluated in small animal patients and is the least expensive. In dog studies, lipid-complexed amphotericin B was determined to be 8 to 10-fold less nephrotoxic than conventional amphotericin B. The decreased toxicity is due to decreased renal cell uptake, reduced tubular toxicity, reduced free amphotericin in solution in plasma, and a selective transfer of amphotericin directly to fungal cell membranes. The reduced toxicity allows higher cumulative doses to be used, which increases drug efficacy. This increase in efficacy is also thought to be related to rapid uptake of lipid complexes by phagocytic cells of the reticuloendothelial (RE) system, which allows sites of inflammation and organs with high RE system activity such as liver, spleen, and lung to receive higher doses of amphotericin B despite minimal renal uptake.

Clinical trials in people have documented improvement in treatment outcomes for many types of fungal infections. ABLC has been used successfully to treat blastomycosis in dogs without significant nephrotoxicity being noted.[9] ABLC can be used in dogs at a dose of 1 to 1.5 mg/lb (2 to 3 mg/kg) intravenously three times a week to a cumulative dose of 24 to 27 mg/kg. Azotemia is rare.

174.1.2 Oral Azole Antifungal Drugs

The azoles are classified as imidazoles (ketoconazole [Nizoral Janssen]) or triazoles (fluconazole [Diflucan Pfize] and itraconazole [Sporanox Janssen]), according to whether they contain two or three nitrogen atoms, respectively, in the five-member azole ring. Ketoconazole and itraconazole have similar pharmacologic profiles, but fluconazole is unique because of its comparatively small molecular size and low lipophilicity. The azole antifungal agents act by inhibiting ergosterol synthesis through interaction with 14-α-demethylase, a cytochrome P-450 enzyme that is necessary for the conversion of lanosterol to ergosterol. Similar interaction in mammalian cells with enzymes dependent on cytochrome P-450 also mediates some of the major toxic effects. The imidazoles are much more potent inhibitors of mammalian cell cytochrome P-450 than are the triazoles. Other antifungal effects include inhibition of endogenous respiration, toxic interaction with membrane

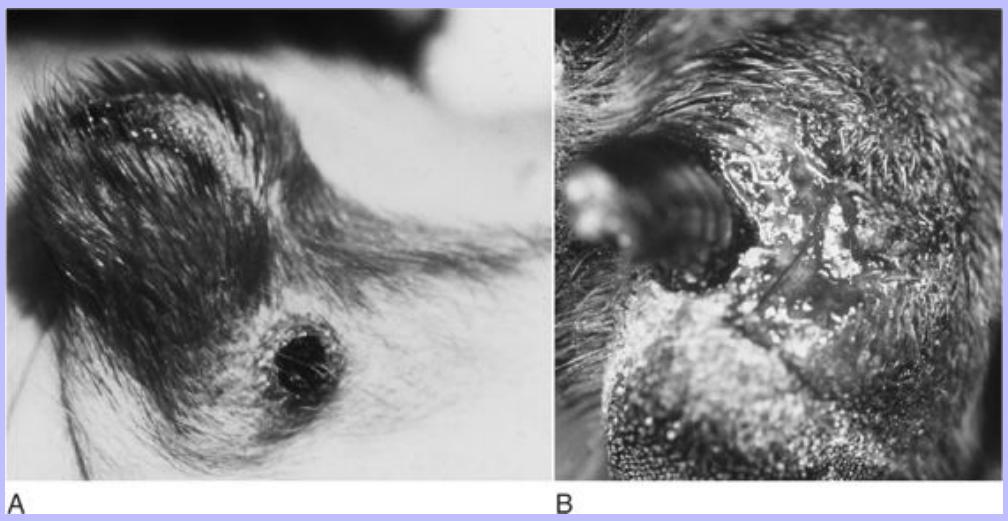
phospholipids, and inhibition of morphogenetic transformation of yeasts to the mycelial forms. Some of the azole antifungal drugs, especially itraconazole and ketoconazole, are potent immune-suppressive agents, suppressing T-lymphocyte proliferation in vitro. Ketoconazole has anti-inflammatory properties that are probably mediated through inhibition of 5-lipoxygenase activity.

Ketoconazole and itraconazole are weak bases that require an acid environment for maximal oral absorption. Antacid administration inhibits oral bioavailability, and the bioavailability of itraconazole is two to three fold higher when taken with food. Recently, itraconazole has been solubilized in cyclodextrins in an effort to increase its absorption after oral dosing and to allow development of a parenteral formulation. Pharmacokinetic studies in both humans and cats have demonstrated increased absorption of itraconazole after administration of the oral solution in comparison to capsules. Both the oral solution (10 mg/mL) and the parenteral formulation (200 mg ampules diluted in 50 mL 0.9% sodium chloride for intravenous administration) are currently available.

Fluconazole is not affected by gastric pH, and food does not affect its oral bioavailability. Peak plasma concentrations of itraconazole and fluconazole do not occur until 6 to 14 days after treatment is begun. This may account for the clinical lag time often seen between the time the drug is started and the time the patient begins to improve. A loading dose can be given for the first 3 days of treatment to reduce the time until steady-state concentrations are attained. Ketoconazole and itraconazole are extensively bound to plasma proteins (>99%), but because of their lipophilicity, both drugs distribute well throughout most tissues; however, 673
concentrations in urine and CSF are typically very low. Neither drug crosses the blood-brain, blood-prostate, or 674
blood-ocular barriers well. Despite this, central nervous system (CNS), prostatic, and ocular fungal infections respond well to treatment with itraconazole. Itraconazole is concentrated in the skin, with delivery being via sebum. Sebum concentrations are 5 to 10 times higher than plasma concentrations, and detectable amounts persist for up to 14 days after the drug is discontinued. Detectable concentrations can be found in the hair and stratum corneum for up to 4 weeks. This property makes itraconazole ideal for treating dermatophyte infections and other fungal infections with cutaneous manifestations. Fluconazole is minimally protein bound and highly water soluble and distributes similarly to free water. High concentrations can be found in urine, CSF, and ocular fluids, and the drug crosses the blood-brain, blood-prostate, and blood-ocular barriers well. Ketoconazole and itraconazole are extensively metabolized in the liver and excreted in the bile and, to a lesser extent, in the urine. In contrast, fluconazole is minimally metabolized, and approximately 80% is excreted unchanged in the urine; consequently, the dose of fluconazole should be reduced in animals with decreased GFR.

The azole antifungal agents are widely used in veterinary medicine for treating systemic fungal infections.[2–4,10] Ketoconazole has been effective as a sole therapeutic agent in the management of blastomycosis, histoplasmosis, cryptococcosis, and coccidioidomycosis. However, with the possible exception of coccidioidomycosis, ketoconazole is probably not as effective as amphotericin B. Ketoconazole is primarily used in conjunction with amphotericin B when managing systemic infections, allowing lower doses of amphotericin B to be used and thus limiting nephrotoxicity. Itraconazole and fluconazole are safer and more effective than ketoconazole and can be used as sole agents in the management of most systemic mycoses. Itraconazole appears to be more effective than fluconazole in most situations, but fluconazole may be superior in the management of cryptococcosis and CNS, prostatic, and urinary tract infections. Itraconazole is the treatment of choice for blastomycosis in dogs and probably cats. Itraconazole has proven very effective as a sole treatment agent for histoplasmosis in cats.[3] The authors have found itraconazole to be effective in treating about 15% of dogs with GI pythiosis, despite the fact that *Pythium insidiosum* does not contain significant concentrations of membrane ergosterol. In treating most systemic fungal infections, a lag occurs between the initiation of treatment and clinical improvement. In severely affected animals, amphotericin B should probably be used initially or in conjunction with the triazole during this lag period.

Figure 174-1 **A**, Lesion on the prepuce of a dachshund being treated for blastomycosis with itraconazole. The lesion is caused by an itraconazole-induced cutaneous vasculitis. **B**, Paronychial lesion caused by an itraconazole-induced cutaneous vasculitis in a Doberman pinscher.



The dose of ketoconazole is 4.5 to 13.6 mg/lb (10 to 30 mg/kg) divided twice a day. Side effects are often limiting, especially at higher doses. Fluconazole (1 to 4.5 mg/lb; 2.5 to 10 mg/kg) and itraconazole (2.2 to 4.5 mg/lb; 5 to 10 mg/kg) are usually better tolerated. Pharmacokinetic studies of itraconazole have been performed in cats.[11] Based on these studies, the oral itraconazole solution is preferred to the capsules, with a 24-hour dosing interval being sufficient at 4.5 mg/lb (10 mg/kg). Steady-state concentrations take up to 3 weeks to achieve. Most adverse effects of itraconazole are related to high serum concentrations, and animals that exhibit adverse effects usually do well on half the original dose. Adverse effects of the azole antifungal agents are similar across the class. Ketoconazole is the least tolerated, and itraconazole appears to be the best.
Dose-related GI side effects (anorexia and vomiting) are most common, especially in cats. When these occur, dividing the dose into two treatments or reducing the dose may be of benefit. Azole-induced anorexia in cats is often ameliorated by the use of appetite stimulants such as oxazepam or cyproheptadine. Liver enzymes should be periodically monitored in animals being treated with azole antifungals. Asymptomatic increases in transaminase concentrations are seen in about half of animals treated with itraconazole, but this does not necessitate a change in therapy unless the animal also has anorexia, vomiting, depression, or abdominal pain. Enzyme concentrations often return to normal over time without intervention. Symptomatic hepatotoxicity is occasionally seen with ketoconazole use but is unusual after fluconazole or itraconazole administration.
Cutaneous reactions are seen in approximately 7% of dogs receiving itraconazole at a dose of 4.5 mg/lb (10 mg/kg).[2] A local ulcerative dermatitis due to a cutaneous vasculitis (Figure 174-1) usually resolves shortly after the drug is discontinued. More severe reactions such as erythema multiforme or toxic epidermal necrolysis are rare. Thrombocytopenia has been associated with fluconazole use in people but has not been documented in animals. Adrenal insufficiency is possible with ketoconazole use. Azole interference with the activity of hepatic

microsomal enzymes can lead to increased concentrations of coadministered drugs such as cyclosporine, digoxin, phenytoin, sulfonylureas, and warfarin.

The emergence in human patients of itraconazole-resistant fungal pathogens has prompted a search for new triazoles with greater potency. One of these newly developed triazoles, voriconazole, has recently gained FDA approval and is available to veterinarians. Voriconazole (Vfend™, Pfizer) is a fluconazole derivative that has potent in vitro and in vivo activity against common endemic and opportunistic fungal pathogens, including molds other than the zygomycetes. It has demonstrated efficacy for invasive aspergillosis and oropharyngeal candidiasis in phase III clinical trials and can be administered either orally or intravenously. Its indications in human patients are for the treatment of invasive aspergillosis and other infections caused by molds (such as *Fusarium*) in immunocompromised individuals. Unfortunately, its high cost makes it unlikely to be used extensively in veterinary patients.

674
675

174.1.3 Flucytosine

Flucytosine is a synthetic antifungal drug with activity attributed to disruption of protein synthesis by inhibition of DNA and RNA synthesis. The drug is synergistic with amphotericin B and is used almost exclusively as an adjunct to amphotericin B in the treatment of cryptococcosis in cats. Flucytosine has good oral bioavailability. It is widely distributed and crosses the blood-brain barrier. The most common side effects are diarrhea, anorexia, and vomiting. Dose-dependent bone marrow suppression manifesting as neutropenia, thrombocytopenia, or pancytopenia is a less common but more signi-ficant toxicity. Cutaneous or mucocutaneous drug eruptions consisting of depigmentation followed by ulceration, exudation, and crust formation (occurring most frequently on the scrotum and nasal planum) have been described in a series of dogs. The dose of flucytosine used in cats is 125 to 250 mg orally divided two to four times a day.

174.1.4 Allylamines

Terbinafine is a synthetic allylamine antifungal drug that interferes with squalene epoxidase and is a potent inhibitor of ergosterol biosynthesis. Squalene accumulation in the fungal cell may account for the drug's fungicidal activity. A keratinophilic compound that is well distributed in skin, it has been used primarily for the treatment of dermatophytosis and onychomycosis in both human and veterinary patients. It may also have efficacy for the treatment of sporotrichosis. The efficacy of terbinafine for invasive or systemic fungal infections has not been well evaluated. However, the authors' clinical observa-tions support the use of this drug in combination with itraconzole for the medical treatment of pythiosis when complete surgical resection of infected tissues is not possible. Potential side effects of terbinafine include GI toxicity, cutaneous reactions, and hepatitis. The drug dose ranges from 2.5 to 9 mg/lb (5 to 20 mg/kg) orally once daily.

174.1.5 Chitin and Glucan Synthesis Inhibitors

Drugs that inhibit the synthesis of chitin or β-glucan, two substances important to the structural and functional integrity of the fungal cell wall, hold promise as antifungal therapeutic agents because their targets are unique to fungi. Chitin synthase inhibitors include lufenuron [program] Novaris (a nonspecific inhibitor of chitin synthase) and drugs in the nikkomycin class, which are competitive inhibitors of chitin synthase. Although one drug in this class (nikkomycin Z) has been highly effective for the treatment of coccidioidomycosis in animal models, the spectrum of activity of nikkomycins for other systemic mycoses is limited and they are no longer being developed. Lufenuron has not been well-evaluated for the treatment of systemic mycoses in animals, but the limited spectrum of the nikkomycins suggest that the usefulness of lufenuron will be limited.

Echinocandins and pneumocandins, which are β-glucan synthase inhibitors in the new lipopeptide class of antifungal agents, hold perhaps the greatest promise for changing the way that clinicians will treat systemic mycoses in the next decade. The most studied of these agents, caspofungin (Cancidas®, Merck) is a potent broad-spectrum parenteral formulation that has potent activity against *Aspergillus* spp. and *Candida* spp. In addition, it is highly effective for the treatment of *Pneumocystis carinii* pneumonia because of its ability to prevent development of the glucan-rich cyst form. The primary limitation of this class of antifungals is its ineffectiveness against *Cryptococcus neoformans*, which contains very little glucan synthase. To date, the use of caspofungin in veterinary patients has not been evaluated, and its extremely high cost will certainly limit its otherwise tremendous potential.

174.2 SPECIFIC SYSTEMIC MYCOSES

174.2.1 Blastomycosis

Blastomycosis is a systemic fungal infection that usually originates in the lungs and then disseminates to the lymphatics, skin, eyes, bones, and other organs. The dog is most commonly affected. Young, male, large breed dogs (especially sporting breeds and hounds) living near water are at an increased risk.[12] In endemic areas, blastomycosis usually occurs as a sporadic event, but outbreaks are occasionally observed in both dogs and people.[13–15] Epidemiologically, outbreaks can often be traced back to a common point source of exposure to a focal area in the environment from which infective spores had been aerosolized for a short time. Confirmation of the source is rarely achieved by organism isolation because of the transient nature of the environmental contamination and the difficulties inherent in laboratory isolation.

The dimorphic fungus *Blastomyces dermatitidis* is the causative agent of blastomycosis. In infected tissue or when cultured at 37°C, the organism is a thick-walled yeast that reproduces by budding. Most often, organisms in tissue have a single bud, attached to the mother cell by a broad base. When cultured at 25°C, mold colonies grow slowly and contain branching, septate 1 to 2 μm mycelia that form round to piriform 2 to 10 μm conidia. In nature, *Blastomyces dermatitidis* is probably a soil saprophyte, but the reservoir remains unresolved because the organism can rarely be cultured from the environment. When cultured, it is usually cultured from wet, acidic or sandy soil containing decaying wood, animal feces, or other organic enrichment.[16] Moisture appears to be important to growth and transmission.

Disease occurrence is reported primarily in a geographically restricted distribution that follows the Mississippi, Ohio, Missouri, Tennessee, and St. Lawrence Rivers, the southern Great Lakes, and the southern Mid-Atlantic states (Figure 174-2). Within these geographic regions, infections are generally limited to smaller geographic pockets, with most affected animals living within a quarter of a mile of water.[15,17] It is not unusual for one veterinary practice within an endemic area to diagnose blastomycosis commonly, whereas another practice located within the same county rarely encounters the infection.

174.2.1.1 Pathophysiology

Blastomycosis is not a contagious disease. It follows contact with the organism in the environment. Infection usually occurs via a respiratory route after the host inhales infective conidiophores. Rarely, disease may be seen after direct inoculation.[18] The incubation period varies from 5 to 12 weeks. Rain, dew, fog, or mist may play a critical role in liberating conidiophores from the environment. In addition, activities that disrupt the

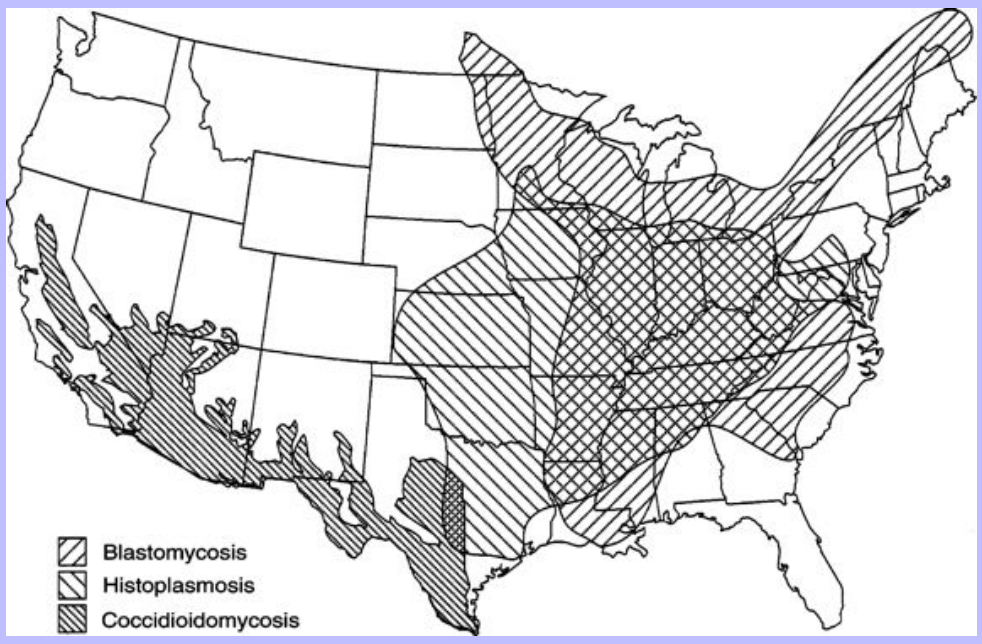
soil such as digging or construction may play a role in the aerosolization of spores. After inhalation, conidia are phagocytized by alveolar macrophages and transform from the mycelial phase to the yeast phase.

The yeasts stimulate local cell-mediated immunity, which results in a marked suppurative to pyogranulomatous inflammatory response. In some cases the cell-mediated immune response controls the infection locally; in others, phagocytized yeasts are transported into the pulmonary interstitium, where they gain access to both the lymphatics and the vascular system.

675

676

Figure 174-2 Areas in the United States endemic for blastomycosis, coccidioidomycosis, and histoplasmosis.



Hematogenous and lymphatic dissemination then results in multisystemic pyogranulomatous disease. Although dissemination can be to any organ system, the lymph nodes, eyes, skin, bones, subcutaneous tissues, and prostate are common organs affected in dogs[2,17,19]; skin, subcutaneous tissues, eyes, CNS, and lymph nodes are most commonly affected in cats.[20]

The immune response determines the severity of clinical disease, but blastomycosis is not considered an opportunistic infection. Antibody production occurs in most but not all cases, with the highest titers usually found in dogs with severe disseminated disease. Antibodies are not considered protective but can be used as a clinical marker of recent exposure or current disease. Recovery from infection is dependent on cell-mediated immunity. An adequate immune response may result in mild respiratory disease that resolves spontaneously. If dissemination has occurred, disease may be obvious in other organ systems, even without apparent pulmonary involvement. A poor immune response may result in severe pulmonary and disseminated disease.

174.2.1.2 Clinical Signs

Bluetick coonhounds, treeing-walker coonhounds, pointers, and Weimaraners have the highest risk of infection.[12] Males are affected more commonly than females, and although any age dog can be affected, those in the 2-to 4-year age group have the highest incidence of disease. Exposure to possible environmental sources of infection, close proximity to water, and the likelihood of being housed in outdoor kennels probably explains the breed association. Clinical findings in animals with blastomycosis vary greatly because of the multisystemic nature of the disease. One or more organ systems may be involved.

Nonspecific signs such as anorexia, depression, weight loss, cachexia, and fever are common. Approximately 40% of dogs are febrile, and dogs with chronic pulmonary disease are most likely to be cachectic. Because the lungs serve as the portal of entry for the *Blastomyces* organism, it is not surprising that pulmonary signs are seen in 65% to 85% of affected dogs. Signs of pulmonary involvement range from mild respiratory distress when exercised to severe dyspnea at rest. Hypoxemia resulting in cyanosis is seen in the most severely affected cases and has a negative prognostic significance.[2] A dry, hacking cough is common. Mildly affected dogs may initially be diagnosed as having kennel cough. Enlarged perihilar lymph nodes compressing primary bronchi, as well as infiltrative bronchointerstitial and alveolar disease, contribute to the cough. Rapid, shallow respiratory efforts may be noted and can be caused by pleural effusion or pleuritic pain. Chylothorax, solid granulomatous masses, and pulmonary thromboembolism are uncommonly reported complications of blastomycosis.

Diffuse lymphadenopathy is seen in about 40% to 60% of dogs with blastomycosis. The lymph node enlargement can be marked and may be mistaken for lymphosarcoma if cytology or histopathology is not performed.

Cutaneous signs are reported in about 30% to 50% of affected dogs and are also commonly noted in affected cats. Reported prevalences of skin disease in cases of blastomycosis may underestimate the actual prevalence, because lesions are sometimes small and easily overlooked unless a thorough dermatologic examination is performed. Single or multiple papules, nodules, or plaques that can ulcerate and drain a serosanguineous to purulent exudate characterize typical skin lesions. The nodular lesions are often quite small in dogs, but large abscesses occasionally occur, especially in cats. Paronychia is common in dogs, so the feet and nail beds should be closely examined.

Ocular involvement is noted in 20% to 50% of cases. Posterior segment disease, characterized by chorioretinitis, retinal separation, subretinal granulomas, and vitreitis, usually occurs initially. Approximately 50% of affected dogs have bilateral ocular involvement. Optic neuritis is occasionally noted and may signify more diffuse CNS involvement and a poorer prognosis. Anterior segment disease is usually, but not always, secondary to the posterior segment involvement. It may be characterized by conjunctivitis, keratitis, iridocyclitis, and eventually anterior uveitis and endophthalmitis. Secondary glaucoma is common in dogs with anterior segment disease. Dogs that are blind at the time of initial diagnosis rarely regain vision, even with aggressive treatment and good systemic response. Dogs that have vision and only posterior segment disease at the time of diagnosis have a better prognosis for vision.

676

677

Lameness caused by fungal osteomyelitis or painful paronychia is noted in about 25% of dogs with blastomycosis, and fungal osteomyelitis is noted in about 10% to 15% of dogs with blastomycosis. The pain and swelling are usually noted over epiphyseal regions below the elbow or stifle. Single lesions are more common than multiple lesions. Fungal mono-or polyarthritis is a rare cause of lameness.

The reproductive system is affected in approximately 5% to 10% of affected dogs. Orchitis was noted in 16% of 61 intact male dogs with blastomycosis seen at Louisiana State University. Fungal prostatitis or mastitis is reported in less than 5% of affected dogs.

The nervous system is affected in less than 5% of canine cases but is commonly affected in feline cases (Figure 174-3). Advanced CNS imaging such as computed tomography (CT) or magnetic resonance imaging (MRI) should be considered in any cat diagnosed with blastomycosis, even if obvious neurologic signs are not apparent. The clinical signs associated with nervous system involvement are dependent on which parts of the CNS are involved, but often neurologic localization indicates diffuse or multifocal disease. Other potential sites of infection include cranial mediastinum, liver, spleen, kidney, and nasal cavity.[21]

Feline blastomycosis is less common than canine blastomycosis. The veterinary literature contains only scattered case reports and small case series.[20] Most of the clinical signs observed in dogs are also noted in cats. The main differences are that large abscesses are more common in cats than in dogs, and neurologic involvement is often noted.

174.2.1.3 Diagnosis

Blastomycosis is usually fairly easy to diagnose because of the large numbers of characteristic yeasts found within lesions, especially within infected skin, eyes, and lymph nodes.[17,22]

Complete blood count (CBC) results are often normal. A mild nonregenerative anemia and mature neutrophilia or neutrophilia with mild left shift may be seen. Clinical chemistry results are also often unremarkable. Hypoalbuminemia is the most consistent abnormality. Mild hypercalcemia is noted in up to 10% of cases.[17] Severe hypercalcemia requiring treatment is occasionally seen.

Radiographic assessment can be very helpful in the diagnostic evaluation of a dog or cat suspected of having blastomycosis (Figures 174-4, 174-5, and 174-6). Thoracic radiographs reveal an interstitial pattern in about 70% of canine cases. Although a nodular interstitial pattern is classically observed (41% of cases), diffuse interstitial (24%) and bronchointerstitial (5%) patterns may also be prominent findings. An alveolar or mixed interstitial-alveolar pattern is observed in about 20% of canine cases, and tracheobronchial lymphadenopathy is noted in about 30%. Radiographic patterns mimicking other diseases such as mediastinal mass (8%) or solitary pulmonary mass (8%) are not as common. Pleural effusion (7%) is rarely observed and when present may obscure pulmonary parenchymal changes. Pneumothorax induced by pulmonary blastomycosis is rare. 677
Bone lesions may be noted on radiographs of long bones, especially those of the distal limbs. Lesions are 678
osteolytic and typically occur at the ends of the long bones (Figure 174-7). The forelimbs are affected more commonly than the rear limbs, with most extremity lesions being below the elbow or the stifle. Periosteal proliferation and soft tissue swelling are noted in about 50% of lesions.

Figure 174-3 Cross-sectional magnetic resonance image (MRI) revealing a contrast-enhancing mixed-intensity lesion in the rostral portion of the right cerebral cortex in a cat with blastomycosis.

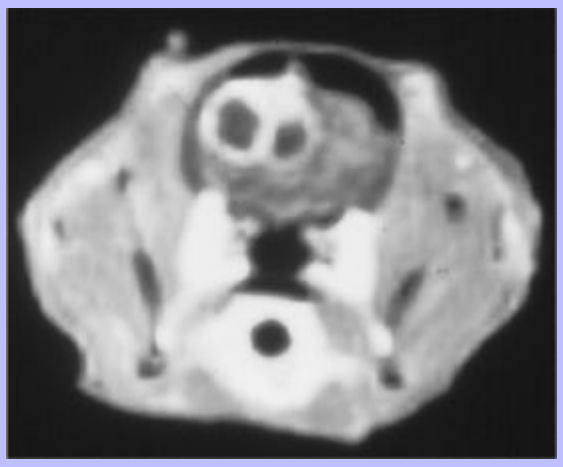


Figure 174-4 Lateral thoracic radiograph revealing a diffuse nodular interstitial pattern in a cat with blastomycosis.

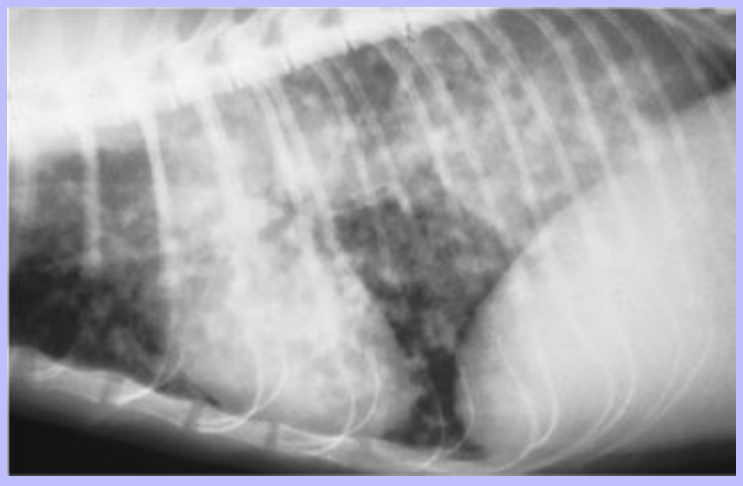

Figure 174-5 Consolidation of the right cranial lung lobe in a cat with blastomycosis. Consolidating and abscessing lesions are often seen in cats with systemic fungal infections.

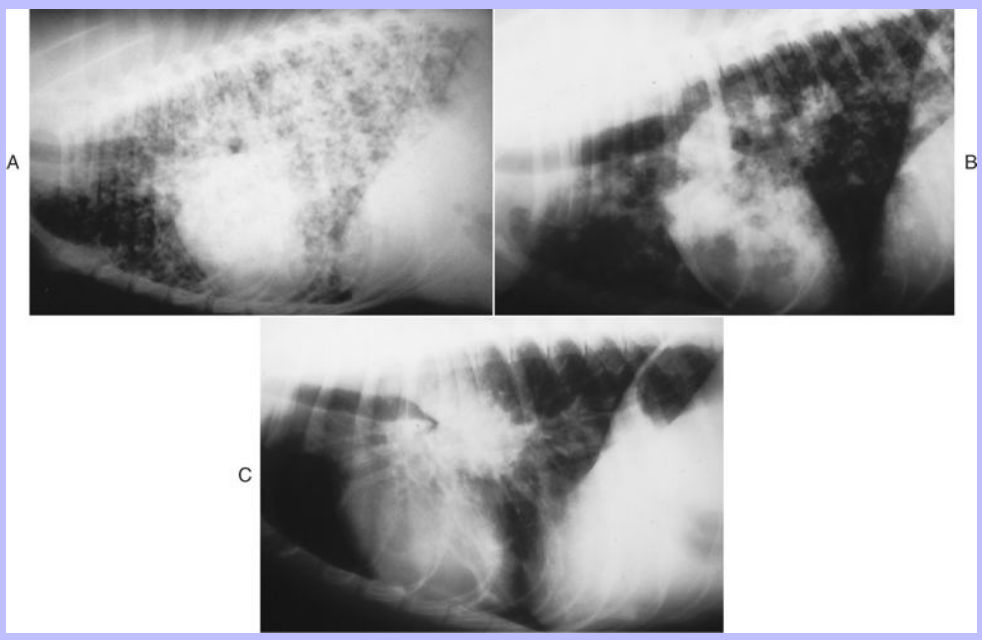
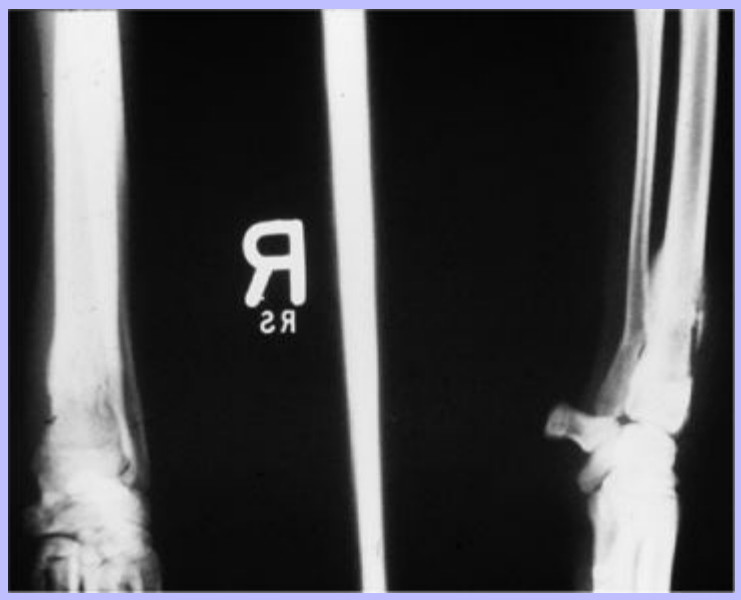
Figure 174-6 **A,** Lateral thoracic radiograph from a dog with blastomycosis revealing the classic "snowstorm" appearance of the nodular interstitial pattern commonly seen in systemic mycotic infections. **B,** Lateral thoracic radiograph from a dog with blastomycosis showing multiple large, ill-defined nodules and a bronchointerstitial pattern. **C,** Lateral thoracic radiograph from a dog with blastomycosis showing perihilar lymphadenopathy and a patchy interstitial pattern. Perihilar lymphadenopathy is common in systemic fungal infections, especially histoplasmosis and coccidioidomycosis.



Definitive diagnosis is made by organism identifica-tion. This can be done by cytology, histopathology, or fungal culture. Cytology from affected tissue typically reveals pyogranulomatous or suppurative inflammation, often with thick-walled yeasts (8 to 12 µm in diameter, with 0.5 to 0.75 µm thick walls) that bud to form daughter cells from a broad base (Figure 174-8).[22,23] The yeast cells lack a capsule, helping to differentiate them from *Cryptococcus*. Skin lesions yield organisms about 80% of the time. This is the easiest and most useful site for cytologic diagnosis. Impression smears, skin scrapings, and fine needle aspirate of nodular lesions can be used. Vitreal aspirates yield organisms from almost all affected eyes, and lymph node aspirates yield organisms approximately 60% of the time. Bone and lung aspirates, transtracheal wash cytology, and bronchoalveolar lavage each yield organisms less than 50% of the time.[17,24] Urinalysis or prostatic wash cytology rarely reveals organisms.

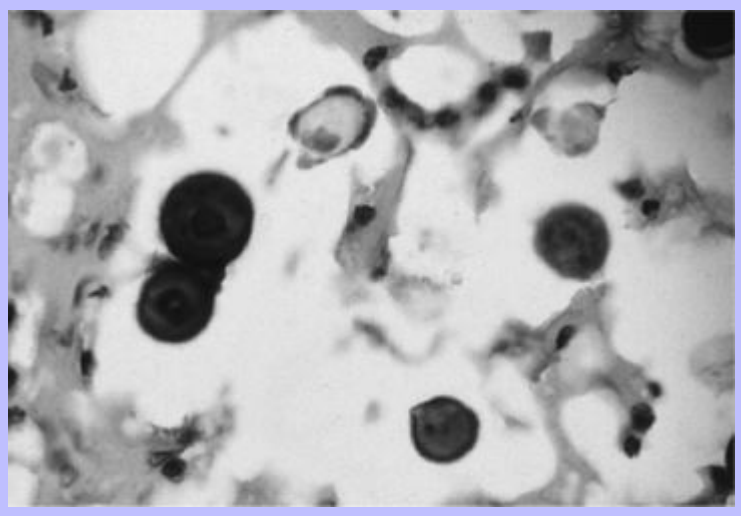
Figure 174-7 Lateral and anteroposterior view of the distal radius, ulna, and carpus from a Brittany spaniel with *Blastomyces* osteomyelitis. The reader should note the bony lysis and periosteal proliferation involving the distal aspect of the proximal radius.



678

679

Figure 174-8 Impression smear from a dog with cutaneous lesions revealing thick-walled, budding yeast typical of *Blastomyces dermatitidis*.



Rarely, organisms may be coughed up and swallowed and appear in the stool on fecal examination.[25] Care must be taken when handling samples that may contain yeast cells. Direct inoculation of organisms from needle-stick injury may result in localized cutaneous disease.[26] This is seen as an occupational hazard in laboratory workers who handle infective material and cultures and in veterinary personnel who sample infected tissue via fine needle aspirate or biopsy. Local inoculation is probably rare as a cause of subcutaneous disease in dogs and cats.

Histopathology is generally characterized by purulent to pyogranulomatous inflammation, with broad-based organisms usually being apparent. Special stains such as periodic acid–Schiff (PAS), Gridley's fungal, and Gomori's methenamine silver (GMS) stain are best for demonstrating organisms. PCR has recently been used to identify organisms in tissue.[27]

Culture is not needed for definitive identification in clinical cases. If tissue is cultured, mycelial growth on Sabouraud's dextrose agar may take 1 to 4 weeks at 37°C, whereas yeast will grow on blood or brain-heart infusion agar in 1 to 2 weeks at 25°C. Culturing the organism from the environment is rarely achieved. The microbiology lab should be alerted if blastomycosis is suspected, because viable cultures of *Blastomyces dermatitidis* present a potential danger of infection for laboratory personnel if the plates are handled inappropriately.[28]

Serology should be used only when a high degree of suspicion for blastomycosis exists and repeated attempts have failed to demonstrate the organisms. Several different types of serologic tests have been evaluated, including agar-gel immunodiffusion (AGID), complement fixation, enzyme-linked immunosorbent assay (ELISA), counterimmunoelectrophoresis, and agar-gel precipitin tests. An AGID test is most commonly used. This test detects antibodies directed against the fungal organism and has a sensitivity and specificity of approximately 90%. Serology may be negative early in the disease course, and in some cases it may revert back to negative as the disease progresses. Antibody titers have not proven useful as an assessment tool in following response to therapy.

174.2.1.4 Treatment

Spontaneous recovery from symptomatic blastomycosis has been reported in people but rarely occurs in dogs and has not been reported in cats. Therefore all cases of symptomatic blastomycosis in dogs and cats should be treated. Itraconazole is presently considered the treatment of choice, except in cases of moderate to severe hypoxemia, when amphotericin B should still be considered the drug of first choice.[2] Clinical cures can be expected in 70% to 75% of treated cases. Treatment failure is most likely in dogs that are hypoxemic or have three or more organ systems affected. The dose of itraconazole that has proven effective is 2.2 mg/lb (5 mg/kg) orally once a day or divided twice a day. The drug should be continued for 2 to 3 months or until active disease is not apparent. Response to itraconazole treatment is minimal during the initial 1 to 2 weeks. A loading dose of 4.5 mg/lb (10 mg/kg) daily for the first 3 days of treatment may minimize this lag time. Treatment for an extra month after signs have resolved does not appear to reduce the likelihood of recurrence. Recurrence occurs in approximately 20% of treated dogs from months to years after treatment has been discontinued.[2,17] Thoracic radiographs are an insensitive tool in monitoring recovery, because significant radiographic abnormalities continue to improve for months after itraconazole treatment has been discontinued. Cats require 4.5 mg/lb (10 mg/kg) once a day or divided twice a day, and longer courses of treatment are usually required.

Ketoconazole is effective in less than 50% of cases at an oral dose of 4.5 to 13.6 mg/lb (10 to 30 mg/kg) divided twice daily for a minimum of 3 months. The response rate is much lower, and the relapse rate is higher when compared with treatment with itraconazole; in addition, dogs generally have to be treated longer. Toxicity is more likely with ketoconazole. Fluconazole has not been investigated for the treatment of blastomycosis in dogs and cats. The author's clinical impression is that it is not as effective as itraconazole, and fluconazole is more expensive. Fluconazole has been used successfully at high doses to treat blastomycosis in people.[29] In addition, because fluconazole does not require a low gastric pH for maximal bioavailability and is not affected by the presence or lack of food, it may be a better initial choice in animals that will not eat. Because it is excreted in the urine and crosses the blood-brain, blood-ocular, and blood-prostatic barriers well, it may be a more appropriate treatment choice for urinary tract, prostatic, and CNS infections. Studies evaluating efficacy in these situations in dogs and cats have not been performed, however. Parenteral forms of fluconazole and itraconazole are available and may be useful for treating severely affected or hypoxemic animals in which amphotericin B is not an appropriate option.

Amphotericin B has very good efficacy against *Blastomyces* organisms. It is recommended that amphotericin B be used in combination with itraconazole or ketoconazole for severely affected or hypoxemic animals.

ABLC (Abelcet), a lipid complexed formulation of amphotericin B is recommended. It allows relatively high doses to be used with low toxicity.[9] A dose of 1 to 1.5 mg/lb (2 to 3 mg/kg) intravenously every other day to a total dose of 24 to 27 mg/kg has been recommended for dogs with blastomycosis. ABLC is expensive when compared with the deoxycholate form, but the authors consider it the treatment of choice for severely affected dogs.

The deoxycholate formulation, although much less expensive, carries a higher risk of toxicity. When using this formulation, reconstituted, amphotericin B is mixed with 5% dextrose in water (D5W) and administered as a rapid infusion over 10 minutes or as a longer infusion over 1 to 6 hours. The longer infusion is less likely to cause toxicity. The dose is 0.22 mg/lb (0.5 mg/kg) for dogs, 0.1 mg/lb (0.25 mg/kg) for cats, intravenously every other day to a total dose of 1.8 mg/lb (4 mg/kg) when used in combination with azole antifungal drugs. A higher dose of 0.22 to 0.45 mg/lb (0.5 to 1 mg/kg) to a total dose of 3.6 mg/lb (8 mg/kg) is recommended in dogs if amphotericin B is the sole treatment agent. The BUN or creatinine should be monitored before each treatment, and amphotericin B should be discontinued if the dog or cat becomes azotemic (BUN >50 mg/dL, creatinine >3 mg/dL). The efficacy of amphotericin B when combined with ketoconazole or itraconazole is equal to that seen with itraconazole alone, but side effects are much more likely.

679

680

Ancillary therapy in hypoxemic animals should include oxygen, bronchodilators, and possibly antibiotics. Anterior uveitis should be treated with topical steroids and atropine; secondary glaucoma with dichlorphenamide (0.9 to 1.8 mg/lb [2 to 4 mg/kg], orally two to three times a day). Atropine should not be used in animals with glaucoma.

Approximately 70% to 75% of dogs treated with either itraconazole or ketoconazole-amphotericin B combination respond completely to therapy. Dogs that die are usually those with severe respiratory disease and hypoxemia. Dogs that live through the first 10 days of therapy generally do well. Hypoxemia and the involvement of three or more systems are poor prognostic factors.[2] Relapse occurs in 15% to 20% of treated dogs. It usually occurs in the first 6 months after treatment but can occur after a year or more. Relapses should be treated as new infections and are no less likely to respond.

174.2.1.5 Public Health Significance

Blastomycosis is not likely to be transmitted from animal to animal or from animal to person. Localized *Blastomyces* infections have occurred after needle-stick injuries when obtaining fine needle aspirate from infected lesions, and laboratory workers can potentially be infected from fungal cultures. Outbreaks in which both people and dogs are affected are due to exposure to a common environmental source rather than to zoonosis.

174.2.2 Histoplasmosis

Histoplasmosis is a systemic fungal infection that usually originates in the lungs and potentially the GI tract, then disseminates to the lymphatics, liver, spleen, bone marrow, eyes, and other organs. A wide variety of mammalian species can be affected, and cats may be more susceptible to infection than dogs. As with most systemic fungal diseases, animals younger than 4 years old are at an increased risk, but any age can be affected.

Histoplasmosis is caused by the dimorphic fungus *Histoplasma capsulatum*. In infected tissue or when cultured at 30° to 37° C, the organism is a yeast. In the environment, *H. capsulatum* is a soil saprophyte that survives a wide range of moistures and temperatures. Nitrogen-rich soils, especially those containing bird or bat guano, appear ideal for supporting growth. The fungus is endemic throughout most of the temperate and subtropic regions of the world. Most cases of histoplasmosis in the United States occur in the central states, with the geographic distribution following the Mississippi, Ohio, and Missouri Rivers. The geographic distribution is wider than that of blastomycosis.

174.2.2.1 Pathophysiology

Histoplasmosis is not a contagious disease. Infection is probably via inhalation or ingestion of infective conidia from the environment. The respiratory system is likely the primary route of infection in cats, humans, and dogs, but the GI system may also be an important route in the dog.

After inhalation or ingestion, conidia transform from the mycelial phase to the yeast phase and are phagocytized by cells of the macrophage monocyte system, where they grow as facultative intracellular organisms. Hematogenous and lymphatic dissemination results in multisystemic disease. Dissemination can be to any organ system, resulting in a granulomatous inflammatory response. The lungs, GI system, lymph nodes, liver, spleen, bone marrow, eyes, and adrenal glands are common organs affected in dogs; lungs, liver, lymph nodes, eyes, and bone marrow are most commonly affected in cats. The incubation period is 12 to 16 days in dogs and humans.

The cell-mediated immune response determines the severity of clinical disease, with subclinical infection probably being common. Most cases of infection are sporadic events, but point-source outbreaks of disease are occasionally reported in both dogs and humans. Epidemiologically, these outbreaks are usually associated with exposure to areas heavily contaminated with *Histoplasma* organisms such as chicken coops, bat habitats, or starling roosts.

174.2.2.2 Clinical Signs

Feline histoplasmosis occurs most commonly in cats younger than 4 years of age. No breed or sex predilection exists. Disease in cats is usually insidious in onset and nonspecific, with clinical findings

varying greatly because of the multisystemic nature of the infection. Depression, anorexia, fever, pale mucous membranes, and weight loss are common. Pulmonary involvement, as evidenced by dyspnea, tachypnea, or abnormal lung sounds, is seen in about 50% of affected cats. Cough is uncommon. Hepatomegaly, splenomegaly, or lymphadenopathy is noted in about a third of affected cats. Ocular involvement may result in abnormal retinal pigment proliferation, retinal edema, granulomatous chorioretinitis, anterior uveitis, panophthalmitis, or optic neuritis. Retinal detachment and secondary glaucoma are less common than in animals affected with blastomycosis. Fungal osteomyelitis may cause lameness in one or more limbs. Cutaneous lesions consisting of multiple small nodules that may ulcerate and drain or crust over are noted less commonly than in animals affected with blastomycosis. GI signs other than anorexia are uncommon in cats with histoplasmosis. Oral and lingual ulceration has been reported as an unusual manifestation. Icterus is occasionally seen in cats with hepatic involvement.

Canine histoplasmosis is also most commonly seen in dogs younger than 4 years of age. Male dogs are affected 1.2 fold as frequently as female dogs, and pointers, Weimaraners, and Brittany spaniels may be over-represented. The clinical findings are related to the route of infection and the extent of systemic dissemination. Clinically inapparent infection is probably common after inhalation of organisms. In those dogs showing clinical signs, findings vary greatly, but GI signs are most common (Table 174-2). Large-intestine diarrhea with tenesmus, mucus, and fresh blood is most common early in the disease course. Small-intestine diarrhea that may be voluminous and associated with malabsorption, protein-losing enteropathy, or both may become apparent as the disease progresses. Nonspecific clinical signs such as fever, anorexia, depression, and severe weight loss are common and may be caused by elaboration of inflammatory mediators such as TNF and interleukin-1 (IL-1). Abnormal lung sounds with or without coughing, tachypnea, or dyspnea are seen in less than 50% of affected dogs. Pleural effusion is seen in rare cases and may contribute to respiratory signs.[30] Splenomegaly, hepatomegaly, and lymphadenopathy are occasionally seen.

174.2.2.3 Diagnosis

A normocytic-normochromic nonregenerative anemia is the most common CBC abnormality. It is caused by chronic inflammation, GI blood loss, and bone marrow infection. Neutrophilia and monocytosis are often seen, but leukocyte counts are variable. Neutropenia or pancy-topenia (or both) is noted in a minority of affected animals, especially in cats. The CBC rarely results in a definitive diagnosis, because *Histoplasma* organisms are only occasionally seen in monocytes or neutrophils and rarely in eosinophils. Thrombocytopenia due to increased use or platelet destruction is seen in as many as one half of affected dogs and one third of affected cats. Serum chemistry abnormalities are nonspecific. Hypoalbuminemia is the most consistent abnormality. Increases in serum alanine aminotransferase (SALT), serum aspartate aminotransferase (SAST), alkaline phosphatase, and total bilirubin may indicate hepatic involvement. Hypercalcemia, although not as common as in dogs with blastomycosis, has been reported. Hypercalcemia is more common in cats than in dogs.[3] It should be noted that hypoalbuminemia lowers total serum calcium and may mask subtle hypercalcemia. Feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV) tests are usually negative in cats.

680

Table • 174-2 Differential Diagnosis for Gastrointestinal Signs Seen in Dogs and Occasionally in Cats With Histoplasmosis

Large-Intestine Disease
Diet-associated colitis
Dietary hypersensitivity
Foreign material–induced colitis
Idiopathic colitis
Lymphocytic-plasmacytic colitis
Eosinophilic colitis
Granulomatous colitis
Histiocytic ulcerative colitis of boxer dogs
Suppurative colitis
Parasitic and protozoal colitis
Trichuriasis (whipworms)
Ancylostomiasis (hookworms)
Strongyloidiasis
Entamebiasis
Balantidiasis
Giardiasis
Bacterial colitis
Salmonella spp.
Campylobacter jejuni
Yersinia enterocolitica, Y. pseudotuberculosis
Mycobacteria
Clostridium perfringens, C. difficile
Candidiasis
Gastrointestinal (GI) pythiosis
Protothecosis
Cecocolic or ileocolic intussusception

Pancreatitis-associated colitis
Small-Intestine Disease
Idiopathic inflammatory bowel disease
Lymphocytic-plasmacytic enteritis
Eosinophilic enteritis
Granulomatous enteritis
Intestinal lymphosarcoma
Parasitic enteritis (ancylostomiasis, toxocariasis)
Chronic giardiasis
Small-intestine bacterial overgrowth
Gastrointestinal (GI) pythiosis
Lymphangiectasia
Exocrine pancreatic insufficiency
Partial intestinal obstruction
Chronic enteropathy of Shar Peis
Immunoproliferative enteritis of basenjis

Thoracic radiographs often reveal a diffuse interstitial or linear interstitial pattern that tends to coalesce to a nodular interstitial pattern (Figure 174-9). Alveolar infiltrates are rarely reported. Hilar lymphadenopathy is common in dogs but unusual in cats. Calcified pulmonary infiltrates or hilar lymph nodes may indicate inactive disease in dogs. Osseous lesions consisting of osteolysis, periosteal new bone formation, and subperiosteal bone proliferation are rarely noted. Bones of the distal appendicular skeleton, especially carpal and tarsal bones, are affected most commonly.

Organism identification is required for definitive diagnosis. The most common means of organism identification is cyto-logy. Cytology from affected tissue reveals pyogranulomatous inflammation, often with numerous small, round to oval intracellular yeast cells (2 to 4 μm in diameter) characterized by a basophilic center and a light halo caused by shrinkage of the cell away from the cell wall during fixation (Figure 174-10). Although multiple *Histoplasma* organisms are usually found within phagocytic cells of the mononuclear phagocyte system, a small number of the organisms are released from cells during slide preparation and may be seen free on the slides stained with a Wright-Giemsa–type stain. Samples for cytology should be collected from tissue with apparent abnormalities. In the cat, aspiration cytology from bone marrow or lymph nodes or cytology from tracheal wash or bronchoalveolar lavage is most likely to yield organisms. In the dog, cytology from rectal scrapings or biopsies and aspiration cytology from bone marrow, liver, lymph nodes, spleen, or tracheal wash or bronchoalveolar lavage are most likely to yield organisms. Buffy coat smears, cytology of pleural or peritoneal effusions, aspirates of lytic bone lesions, and aspirates or impression smears of nodular skin lesions may also yield organisms.

If organisms are not cytologically apparent, histopathology may be diagnostic. Pyogranulomatous lesions with multiple intracellular organisms are usually apparent. Histoplasmosis should be considered when granulomatous hepatitis or other granulomatous or pyogranulomatous disease is seen on biopsy.[31] The yeast does not stain well with routine hematoxylin-eosin (H&E) stains, so special stains such as PAS, Gridley's fungal, and GMS stain are often used to demonstrate organisms.

Fungal culture from affected tissue can be used for diagnosis but is rarely needed in clinical cases. The organism grows as buff-brown mycelial growth on Sabouraud's dextrose agar. It usually takes 7 to 10 days to grow at room temperature. The yeast produces white, moist colonies on blood agar when grown at 30° to 37° C. The cultured organism is of pathogenic potential, which precludes culture attempts in a practice setting.

Serology is presently an ineffective method of diagnosis. Both false-positive and false-negative results are common. Poor correlation between necropsy findings and complement-fixation tests has been seen in multiple studies.

174.2.2.4 Treatment

Pulmonary histoplasmosis may be self-limited, but antifungal treatment is still recommended because of the potential for chronic dissemination. Dogs or cats with other systemic findings indicative of disseminated histoplasmosis usually die without treatment. Treatment protocols are similar to those described for blastomycosis, although they have not been as well studied. Longer treatment times are probably needed in most cases, but this is highly variable, depending on the severity of the infection and the response of the animal.

Itraconazole (4.5 mg/lb [10 mg/kg] orally once a day or divided twice a day) is considered the treatment of choice for feline histoplasmosis. At least 2 to 4 months of therapy is required. Few studies have evaluated the efficacy of itraconazole treatment, but in one study, all eight of eight treated cats were cured.[3] Ketoconazole is effective in about one third of affected cats. The addition of amphotericin B to ketoconazole treatment regimens may improve the efficacy, especially in severely affected cats. Fluconazole is likely effective but has not been well studied.

In dogs with histoplasmosis, ketoconazole has been described as the treatment of choice. Amphotericin B should be added to the protocol in fulminant cases. Itraconazole or fluconazole is safer and may result in better efficacy than ketoconazole, but evaluation has been minimal. For dogs with GI disease, ancillary therapy should be considered along with antifungal therapy. A highly digestible diet should be fed to dogs with small-intestine involvement, and fiber may be useful in dogs with signs of colitis. Small-intestine bacterial overgrowth may occur in dogs with histoplasmosis and should be treated with tylosin (4.5 to 9 mg/lb [10 to 20 mg/kg] orally twice a day), metronidazole (3.4 to 4.5 mg/lb [7.5 to 10 mg/kg] orally two to three times a day), tetracycline (6.8 to 9 mg/lb [15 to 20 mg/kg] orally three times a day), or amoxicillin (4.5 to 9 mg/lb [10 to 20 mg/kg] orally twice a day). Nonspecific therapy for diarrhea can include loperamide (0.045 to 0.09 mg/lb [0.1 to 0.2 mg/kg] orally twice a day) for small-intestine diarrhea and sulfasalazine (4.5 to 13.6 mg/lb [10 to 30 mg/kg] orally two to three times a day) for large-intestine diarrhea. Ancillary respiratory therapy may include oxygen and bronchodilators in hypoxemic animals and antibiotics in dogs with secondary bacterial pneumonia. Corticosteroids have been recommended for treating dogs with airway obstruction secondary to hilar lymphadenopathy caused by histoplasmosis.[32]

Figure 174-9 Lateral thoracic radiograph of an 8-year-old Siamese cat with a 2-week history of dyspnea caused by *Histoplasma capsulatum* infection. This coalescing pattern of interstitial infiltrates is commonly seen in cats with pulmonary histoplasmosis.

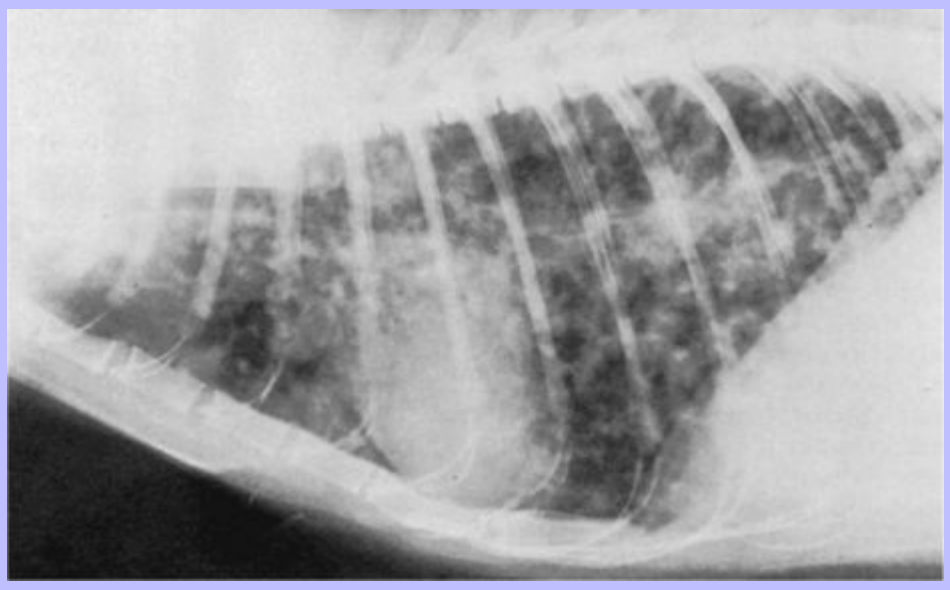

Figure 174-10 Cytology from a bronchoalveolar lavage sample revealing a macrophage containing many round to oval-shaped *Histoplasma* organisms in a cat with histoplasmosis. (Courtesy of Dr. Jan VanSteenhouse.)

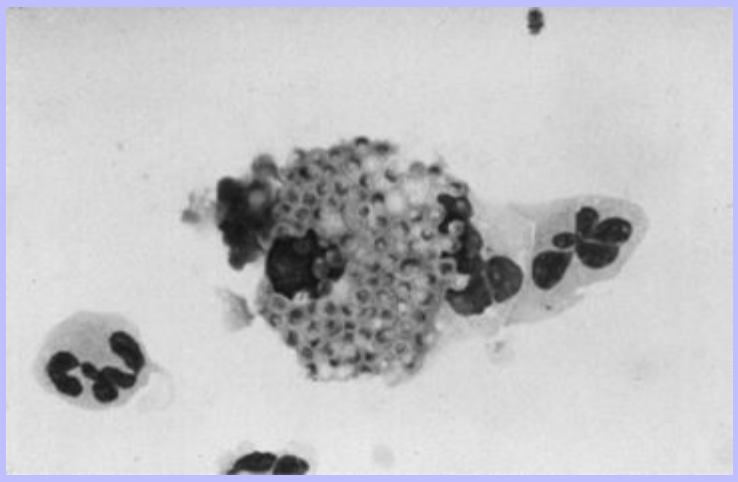

Resolution of clinical signs is the best means of patient monitoring. Rechecks should be performed monthly while dogs or cats are being treated and should include physical and ocular examinations and a chemistry panel to evaluate liver enzymes in animals receiving azole antifungals. Treatment should be continued for 1 month beyond resolution of clinical signs, and animals should be reevaluated 3 and 6 months after discontinuing therapy to assess for relapse. Serology is not useful in monitoring response to therapy or evaluating for relapse.

The prognosis is good for dogs with only pulmonary signs, but dogs with GI or severe dissemination have a guarded prognosis. The prognosis is fair to good for cats treated with itraconazole, although long-term therapy may be required. Severely debilitated cats have a guarded prognosis.

174.2.3 Cryptococcosis

Cryptococcosis is an opportunistic systemic fungal infection of worldwide significance that usually originates in the nasal cavity, paranasal tissues, or lungs. It can then disseminate, most commonly to the skin, eyes, or CNS. Disease occurs in a wide variety of mammalian species. Among domestic animals, it occurs most commonly in the cat, in which it is the most common of the systemic mycoses. Unlike the other systemic mycoses, cryptococcosis does not follow strict geographic boundaries but is most common in the Southeastern and Southwestern United States, Southern California, and the east coast of Australia.

Cryptococcosis is caused by *Cryptococcus neoformans*, a saprophytic, round, yeastlike organism with a restricted ecologic niche. *C. neoformans* var. *neoformans* is the subspecies that most commonly causes disease and is environmentally associated with pigeon droppings or other avian habitats. *C. neoformans* var. *gattii* is a second subspecies that is capable of causing disease and is associated with bark and leaf litter of certain eucalyptus trees. In infected tissue, and often when cultured, the organism is a variable-sized yeast (3.5 to 7 μm) with a large heteropolysaccharide capsule (1 to 30 μm). Both subspecies have been shown to cause disease in cats and humans. *C. neoformans* reproduces primarily by budding from a narrow base.

The pigeon is thought to be the most important vector of *C. neoformans*. The *Cryptococcus* organism can be found in high numbers in pigeon roosts, barn lofts, haymows, and along cupolas and cornices where pigeons often sit. In the desiccated state, the *Cryptococcus* organism may be no larger than 1 μm and may survive up to 2 years.

682

683

174.2.3.1 Pathophysiology

Cryptococcosis is not a contagious disease. Infection occurs most commonly via inhalation of yeast from the environment. Debris and droppings in and around avian habitats, especially pigeon habitats, contain the largest numbers of *Cryptococcus* organisms. Most yeasts are probably too large to be inhaled into the lungs and settle out in the nasal cavity or nasopharynx, where they can produce disease or result in animals becoming asymptomatic carriers of the organism. In one study, cryptococcal organisms could be cultured from nasal washings in 14% of asymptomatic dogs and 7% of asymptomatic cats.[33] The small, desiccated forms of the yeast are also infective and can be inhaled into the small airways and alveoli, leading to pulmonary disease. After inhalation into the nasal cavity, paranasal sinuses, or lungs, cell-mediated immune response results in granuloma formation. Dissemination can occur by either direct extension or hematogenous spread. Direct extension from the nasal cavity through the cribriform plate to the CNS or to the paranasal soft tissues and skin is common. Although dissemination can be to any organ system, the skin, eyes, and CNS are most commonly affected.

Lesions consist of either granulomatous inflammation with few organisms or gelatinous masses of organisms with little inflammation. The large capsule surrounding the cryptococcal organism contributes to pathogenicity by inhibiting phagocytosis, plasma cell function, and leukocyte migration. As with the other systemic mycoses, the immune response determines the severity of clinical disease. Antibodies are readily produced by the humoral immune system but are not considered protective. Recovery, therefore is dependent on cell-mediated immunity. Most human cases of cryptococcosis are associated with immune suppression, especially lymphoreticular neoplasia and AIDS. However, immune suppression has not been as apparent in most affected cats and dogs. An association with FeLV and FIV infections in cats has been reported, and chronic glucocorticoid use has been implicated as a predisposing factor in both cats and dogs.[4,30,34,35]

174.2.3.2 Clinical Signs

Cats are more commonly affected by cryptococcosis than dogs. No apparent breed, sex, or age predilection exists in cats. Clinical findings are usually related to upper respiratory, nasopharyngeal, cutaneous, ocular, or CNS involvement. Unlike in other systemic mycoses, the lungs are not commonly affected. Nonspecific signs such as depression and anorexia are common in chronic cases, but fever is uncommon. Upper respiratory signs related to nasal cavity involvement are seen in 50% to 80% of affected cats. In these cats, sneezing and snuffling are common, and unilateral or bilateral mucopurulent nasal discharge with or without blood is typically seen. Proliferative soft tissue masses or ulcerative lesions within the nasal cavity or over the bridge of the nose are seen in approximately 70% of cases with upper respiratory involvement (Figure 174-11). Oral ulcerations are occasionally noted but are not common. Nasopharyngeal mass lesions causing snoring, stertor, and inspiratory dyspnea are occasionally noted.[36] The skin or subcutaneous tissues are affected in approximately 40% to 50% of infected cats. Primary lesions include papules or nodules that may ulcerate and drain. Multiple lesions are typical, and regional lymphadenopathy is common. Hematogenous spread from the respiratory system may result in lameness secondary to osteomyelitis, renal failure secondary to renal disease, and generalized lymphadenopathy.

The eyes are affected in 20% to 25% of infected cats, especially those with CNS involvement. Granulomatous chorioretinitis with or without exudative retinal detachment is the most common ocular manifestation and can lead to panophthalmitis. Less often, optic neuritis can be seen, resulting in blindness. Anterior uveitis is not as common as posterior segment disease. CNS involvement is reported in approximately 20% of affected cats. This may be an under-representation of the actual number of cases with nervous system involvement.[35] The forebrain is most commonly affected, because invasion through the cribriform plate is thought to be common. Signs may include depression, behavior changes, seizures, circling, ataxia, blindness, head pressing, cranial nerve deficits, and paresis. Nasopharyngeal granulomas may occlude the auditory tube resulting in otitis media interna and resultant peripheral vestibular signs.[37] Cats with concurrent FeLV or FIV infection tend to be more severely affected and may be more likely to develop neurologic or ophthalmic signs.

Figure 174-11 Nasal cryptococcosis in a cat. (Courtesy Dr. Carol Foil.)

Canine cryptococcosis is typically seen in dogs younger than 4 years of age. No apparent sex predilection exists, and American cocker spaniels, Labrador retrievers, Great Danes, and Doberman pinschers appear to be over-represented. In dogs, clinical findings are most often related to CNS, upper respiratory, ocular, or cutaneous involvement.[38] As in cats, depression and anorexia are common but fever is not. CNS involvement is reported in approximately 50% to 80% of affected dogs. The brain is affected in most of these dogs.[39,40] The spinal cord may be affected along with the brain, and rarely the spinal cord alone is affected, causing signs consistent with either meningitis or an extradural compressive lesion.[41] Signs of nervous system involvement may include mental depression, vestibular syndrome, ataxia, cranial nerve deficits (especially cranial nerves V, VII, and VIII), seizures, paresis, blindness, hypermetria, and cervical pain. In dogs with CNS signs, other systems are usually affected as well, reflecting multisystemic dissemination.

The upper respiratory system or perinasal tissues are affected in approximately 50% of dogs with cryptococcosis (Figure 174-12).[38] The caudal nasal cavity and frontal sinuses are affected more commonly than the rostral nasal cavity. Signs may include upper airway stridor, nasal discharge and sneezing, epistaxis, or firm swellings over the bridge of the nose. The eyes or periorbital tissues are affected in approximately 20% to 40% of dogs with cryptococcosis. Granulomatous chorioretinitis with or without exudative retinal detachment is the most common ocular manifestation and can lead to panophthalmitis. In addition to chorioretinitis, fundic examination may reveal retinal hemorrhage or retinal scarring. Optic neuritis may be noted as a cause of blindness. As with the other systemic mycoses, anterior uveitis is less common than posterior segment disease. The skin is affected in approximately 10% to 20% of dogs with cryptococcosis. Subcutaneous nodules with ulcerative draining lesions, often on the head, feet, nail beds, and mucous membranes of the mouth, occur most commonly. Proliferative lesions in the ear canals may result from cryptococcal otitis externa. Direct extension from the ears to the CNS may occur. Multiorgan dissemination is more common in dogs than in cats. Disease may be subclinical or may result in clinical signs referable to the organ systems affected.

174.2.3.3 Diagnosis

Hematology and clinical chemistries are often normal in animals with cryptococcosis. Mild nonregenerative anemia and mature neutrophilia or neutrophilia with a mild left shift may be seen. Because the nervous system is so commonly affected, CSF tap for culture and cytology should be considered. CSF commonly yields increased opening pressure, increased protein, and mixed mononuclear and neutrophilic pleocytosis. Organisms are visualized in approximately 90% of dogs with CNS cryptococcosis.[42]

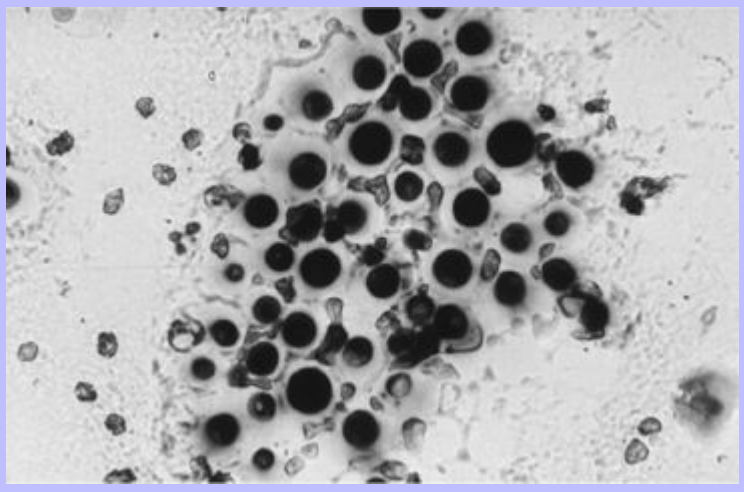
Nodular infiltrates, an interstitial pattern, pleural effusion, and tracheobronchial lymphadenopathy are occasionally seen on thoracic radiographs. Nasal radiographs may demonstrate increased soft tissue density and bone destruction in the nasal passages and frontal sinuses.

Organism identification allows for definitive diagnosis and can usually be made cytologically or histologically. Cytology from affected tissue is the quickest and easiest means of identifying cryptococcal organisms. Nasal swabs, exudate from cutaneous lesions, aspirates of masses, subretinal or vitreal aspirates, and CSF often reveal organisms. Organisms are apparent in approximately 75% of cases. The large capsule makes identification easy (Figure 174-13).

Gram's stain is useful in looking for cryptococcal organisms, because the cells retain the crystal violet and the capsule stains lightly red with the safranin. If India ink is used, the organism and capsule appear unstained and silhouetted against the black background (Figure 174-14). Care must taken in interpreting India ink preparations, as lymphocytes, fat droplets, and aggregated ink particles may be confused with the organism. Budding is occasionally noted. The thin wall and the large capsule differentiate *Cryptococcus* from *Blastomyces*.

Histopathology should be used if cytology fails to identify organisms. Nodular to diffuse granulomatous lesions or areas of degeneration with little inflammation are seen in infected tissue. Yeastlike organisms are usually numerous. Special stains such as PAS, Gridley's fungal, and GMS stain are best at demonstrating organisms. Mucicarmine stains best demonstrate the capsule.

Figure 174-13 Cryptococcal organism noted on fine-needle aspirate cytology from the dog in Figure 174-12. Note the large capsules surrounding the organisms and the minimal inflammatory response.



Cryptococcal organisms grow readily when cultured. The organism can be cultured from infected tissue, exudate, CSF, urine, joint fluid, and blood if large enough samples are submitted. Yeastlike growth occurs in 2 days to 6 weeks on Sabouraud's dextrose agar. Hyphae rarely grow, even at 37° C. Care must be taken in interpreting positive cultures from the nasal cavity, because 14% of asymptomatic random-source dogs and 7% of asymptomatic random-source cats were culture-positive in one study.[33] Animals in the previously mentioned study were all negative on serum latex agglutination tests and did not have macroscopic or microscopic findings supportive of cryptococcal infection.

Serology is useful as an inexpensive and noninvasive diagnostic test when cytology has failed to demonstrate organisms. Latex agglutination procedures are used to detect cryptococcal capsular antigen. Antibody titers are not useful diagnostically, because most infected animals do not mount a humoral immune response.[43] The commercially available latex cryptococcal antigen agglutination tests can be used on serum, urine, or CSF. CSF is the best sample to use in animals with neurologic signs, and serum is the best sample to use in animals with upper respiratory or cutaneous signs but without neurologic signs. Most cases are positive with titers between 1:10 and 1:100,000. The median titer in infected cats in one study was 1:1000.[43] False-negative antigen titers are rare but may occasionally be seen in localized disease. False-positive antigen titers are uncommon and are usually related to technique or interfering substances such as rheumatoid factor (RF). The latex agglutination antigen titer tends to correlate well with the extent of disease but does not correlate well with prognosis.[44] It may be used to evaluate the treatment progress.

174.2.3.4 Treatment

Amphotericin B is the most effective drug in vitro against cryptococcal isolates, but both itraconazole and fluconazole have proven to be equally efficacious in treating CNS cryptococcosis in people. Little information is available evaluating amphotericin B in the treatment of cryptococcal infections in dogs and cats. Amphotericin B is synergistic with flucytosine. Flucytosine can be used at a dose of 11.4 to 22.7 mg/lb (25 to 50 mg/kg) orally four times a day and has been used in dogs and cats. The combination of amphotericin B and flucytosine may be especially useful for treating CNS infections. Cryptococcal organisms may rapidly develop resistance to flucytosine, so it has limited efficacy as a sole treatment agent. The dose of flucytosine should be adjusted downward in animals with concurrent renal failure. Toxicity to flucytosine includes ulcerative drug eruptions on the skin (especially on the face) and mucocutaneous junctions, enterocolitis, leukopenia, and thrombocytopenia. Amphotericin B has also been effective when combined with azole antifungal agents.

Subcutaneously administered amphotericin B in combination with azole antifungals or flucytosine has been used to successfully treat both feline and canine cryptococcosis.[45] Amphotericin B (0.22 to 0.36 mg/lb; 0.5 to 0.8 mg/kg) is diluted in 0.45% saline containing 2.5% dextrose (400 mL for cats, 500 mL for dogs <20 kg, 1000 mL for dogs >20 kg) and administered subcutaneously two to three times per week. This protocol may allow larger cumulative doses of amphotericin B to be given with reduced toxicity. Concentrations greater than 20 mg/L of amphotericin B resulted in local irritation and sterile abscess formation; therefore more concentrated formulations of amphotericin B should not be used subcutaneously.

Ketoconazole is variably effective as a sole treatment agent but is ineffective in cases with CNS involvement. There were only scattered reports of successful treatment of cryptococ-cal infections in dogs and cats before the availability of the triazole antifungals, but since they became available, successful treatment has been reported more commonly. Fluconazole (50 mg/cat orally twice a day; 2.2 mg/lb [5 mg/kg] orally once to twice a day for dogs) is very effective and is the treatment of choice for cryptococcosis

in cats and probably dogs. Itraconazole (4.5 mg/lb [10 mg/kg] orally daily) is effective in cats and dogs but appears to be less effective than fluconazole. Controlled trials in people have revealed the two drugs to be equally efficacious. Ketoconazole (4.5 to 13.6 mg/lb [10 to 30 mg/kg] orally twice a day) is even less effective but can be used if other drugs are unavailable.

Resolution of clinical signs is the best means of patient monitoring, but serially monitoring latex agglutination antigen titers can significantly augment the clinician's clinical observations.[30,44] Rechecks should be performed monthly while dogs or cats are being treated and should include a chemistry panel to evaluate liver enzymes in animals receiving azole antifungals and a latex agglutination antigen titer. Sequential titers should differ by two or more dilutions before they are considered significantly different. A decline of two-to fourfold per month during the initial few months of antifungal therapy generally corresponds to an adequate clinical response. Ideally, treatment should be continued until the titer is negative or for at least 2 months beyond resolution of clinical signs. In some animals, detectable cryptococcal polysaccharide antigen persists in the circulation long after the infection has been successfully treated. This is thought to be caused by continued elimination of unviable organisms and capsular material from infected tissues and macrophages. Most of these animals have low titers. High residual titers may indicate insufficient therapy and thus persistence of viable organisms.[30] One author's recommendation is to continue antifungal drug treatment to a titer of less than 1.[44] In cases in which there has been a thirty-twofold decrease and resolution of clinical signs, treatment may be discontinued; however, titers should be reevaluated periodically to ensure that they continue to decline or at least remain stable. Animals should be reevaluated at least 3 and 6 months after discontinuing treatment to assess for relapse. Negative antigen titers are occasionally seen in animals with localized disease, so they do not always indicate clinical cure.

The prognosis is good for cats with extraneural disease, and it is guarded for dogs with any form of the disease and for cats with CNS involvement.

174.2.4 Sporotrichosis

Sporotrichosis is a chronic granulomatous disease of worldwide significance caused by the dimorphic saprophytic fungus *Sporothrix schenckii*. The organism lives as a mycelium in the soil and when cultured at room temperature and as a yeast at body temperature. The mycelia are thin, finely branched, and septate. They produce clusters of conidiophores, which are the infective stage. The yeast form exists in infected tissue and is characterized as pleomorphic round, oval, or cigar-shaped cells that measure 2 by 3 µm to 3 by 10 µm (Figure 174-15). The yeast is fairly characteristic, and a diagnosis can usually be made from a cytologic preparation. Both dogs and cats can be infected. Dogs are infected less commonly and usually have only cutaneous or subcutaneous disease. Cats are infected more frequently and commonly have systemic dissemination.

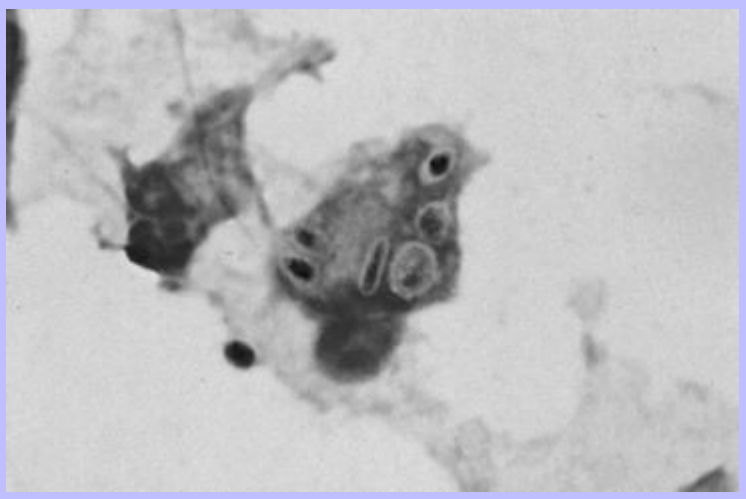
174.2.4.1 Pathophysiology

Infection with *S. schenckii* in dogs and cats usually occurs after trauma that results in inoculation of infective conidiophores. Yeast from cutaneous lesions can be infective and is a potential zoonotic source of infection via contamination of wounds or via scratches or bites. The skin is the primary organ system affected, but dissemination via lymphatics is common in cats and less common in dogs. Immune suppression predisposes to infection and increases the likelihood of dissemination.

Sporotrichosis occurs in three primary forms: (1) cutaneous, (2) cutaneolymphatic, and (3) disseminated disease. In the dog, the infection is usually cutaneous or cutaneolymphatic. Disseminated disease is rare and usually follows immune suppression with corticosteroids. The cutaneolymphatic form is common in the cat, 685 686

and dissemination is seen in more than 50% of feline cases. The lesions in cats are characterized by large numbers of yeasts, making zoonotic transmission more likely from cats than from dogs.

Figure 174-15 Impression smear from a skin lesion on a cat, revealing pleomorphic organisms characteristic of sporotrichosis.



174.2.4.2 Clinical Signs

Most affected cats are younger than 4 years of age, and males are affected approximately twice as commonly as females.[46] Young hunting dogs may be predisposed. Multiple subcutaneous or dermal nodular lesions that occur most commonly on the head, neck, trunk, and distal limbs characterize the cutaneous form of the disease. The tail base may also be involved in cats. The nodules typically ulcerate, drain a purulent exudate, and crust over (Figure 174-16). They are often confused with bite wound abscesses or cellulitis. Lesions on the distal limbs commonly result in regional lymphadenitis, which is manifested as linear ulcerating lesions and regional lymphadenopathy. Lesions in cats may be associated with extensive areas of necrosis. Otitis externa has been reported.

Dissemination may occur and be subclinical or may result in serious systemic disease. Too few cases have been reported to develop a clear picture of a dissemination pattern, but internal lymph nodes, spleen, liver, lungs, eyes, bones, muscles, and CNS have all been affected.

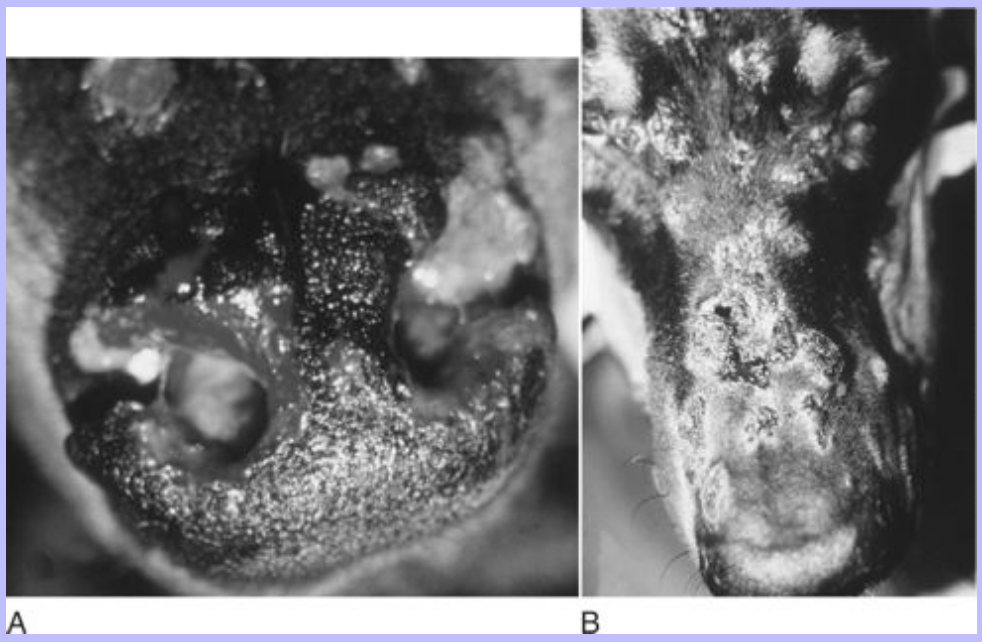
174.2.4.3 Diagnosis

Cytology from skin lesions is the most common means of diagnosis. Lesions from cats contain large numbers of organisms, making diagnosis fairly easy; lesions from dogs usually contain very few organisms. The organisms may be seen intracellularly within macrophages or neutrophils or may be present extracellularly. Culture can be used to make a definitive diagnosis.

Material for culture should include exudate from deep within a draining tract and tissue samples from biopsy specimens. Cultured organisms pose a serious threat to persons working in the laboratory, so the laboratory should be notified whenever a sample is submitted from a dog or cat with suspected sporotrichosis.

Histopathology reveals pyogranulomatous inflammation. Numerous organisms are commonly seen in lesions from cats, even when stained with H&E. Fungal stains such as PAS or immunofluorescent techniques may aid in finding organisms in dogs. Immunofluorescent testing can be performed by the Centers for Disease Control and Prevention in Atlanta, Georgia.

Figure 174-16 A and B, Sporotrichosis affecting the skin and nasal mucosa of a Doberman pinscher.



174.2.4.4 Therapy

Traditionally, sporotrichosis has been treated with potassium iodide, ketoconazole, or combinations of the two. Approximately 55% of treated cats in the literature responded to one or both of these drugs.[46] Itraconazole is the treatment of choice in people and is effective in dogs and cats. It is especially valuable in cats because of the species' tendency to develop iodism on potassium iodide.

The response to itraconazole treatment in cutaneous and cutaneolymphatic cases is generally good. The prognosis must be guarded for disseminated disease, but too few cases have been reported to give a well-informed likelihood of response.

174.2.4.5 Public Health Significance

Canine sporotrichosis is of minimal zoonotic potential, but feline sporotrichosis is a significant zoonotic disease. Veterinarians and veterinary assistants are at the highest risk of infection. Care should be taken to limit contact with exudate and lesions from infected cats. Gloves should always be worn when handling cats suspected of having sporotrichosis, and owners should be advised of the possibility of infection and the need

for strict hygiene. After any contact, gloves should be removed carefully and disposed of, and hands, wrists, and arms should be washed thoroughly with either chlorhexidine or povidone-iodine scrub.

174.2.5 Candidiasis

Candida spp. are normal inhabitants of the GI, genitourinary, and upper respiratory systems. *Candida* may overgrow in cases of immune suppression or prolonged broad-spectrum antibiotic use, especially in wounds, the oropharynx, or the GI tract. Animals with neutropenia are especially predisposed to infection. Infections may be localized, or dissemination may occur via a hematogenous route, resulting in microabscesses at multiple sites.

Localized candidiasis is usually characterized as a nonhealing ulcer covered by a whitish-gray plaque in the oral cavity, in the GI tract, or on the genitourinary mucosa. Chronic moist, exudative lesions may occur on the skin or at the nail beds.

Disseminated disease is typified by fever and the acute appearance of multiple raised erythematous skin lesions in dogs. In dogs, pain is often caused by myositis and osteomyelitis, and other signs are referable to the systems affected. Cats are less likely to have multiple skin lesions. The CBC in systemically affected animals is often characterized by leukopenia and thrombocytopenia. Renal involvement is common, and yeast may be found in the urine, especially in cats.

686

687

Itraconazole and ABLC are considered the treatments of choice, but few reports of successful treatment are available.

174.2.6 Pythiosis

Pythiosis is a devastating and often fatal cause of chronic GI or cutaneous disease in dogs and cats. It is caused by *Pythium insidiosum*, an aquatic pathogen belonging to the class Oomycetes in the Kingdom Stramenopila (Chromista). Recent phylogenetic studies have confirmed that oomycetes are more closely related to algae than to fungi. Chitin, an essential component of the fungal cell wall, is generally lacking in oomycetes, which instead contain predominately cellulose and β-glucan. In addition, oomycetes differ from fungi in that ergosterol is not a principal sterol in the oomycete cell membrane. In the United States, pythiosis is encountered most often in the Gulf Coast states, but has been recognized in animals living as far north as New Jersey, Virginia, Kentucky, and southern Illinois and Indiana, and as far west as Arizona, California, Oklahoma, and Kansas. Globally, pythiosis is most often encountered in Southeast Asia, eastern coastal Australia, and South America.

174.2.6.1 Pathophysiology

The infective form of *P. insidiosum* is thought to be the motile biflagellate zoospore, which is released into aquatic environments and likely causes infection by encysting in damaged skin or GI mucosa. Many dogs with pythiosis have a history of recurrent exposure to warm freshwater habitats. However, some cases are observed in suburban house dogs with no history of access to lakes or ponds. Affected animals are typically immunocompetent and otherwise healthy.

174.2.6.2 Clinical Findings

Pythiosis occurs most often in young, large breed dogs and is especially common in outdoor working breeds such as Labrador retrievers. Affected dogs are presented to the veterinarian more often in the fall, winter, and

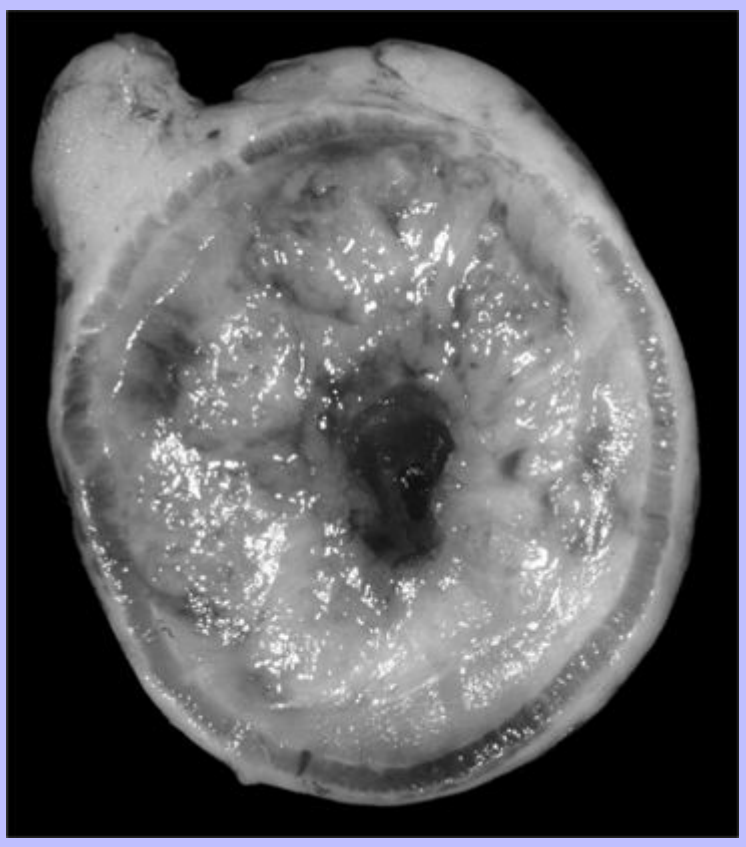
early spring than in the summer months. In cats, specific breed and sex predilections have not been observed in the few cases that have been reported to date. However, of ten cats with cutaneous pythiosis diagnosed through our laboratory since 1999, five were less than 10 months old, with an age range of 4 months to 9 years.

Cutaneous pythiosis in dogs typically causes nonhealing wounds and invasive masses that contain ulcerated nodules and draining tracts, most often involving the extremities, tail head, ventral neck, or perineum.[47,48] Cats with pythiosis may have nasopharyngeal lesions, invasive subcutaneous masses in the inguinal, tail head, or periorbital regions, or they may have draining nodular lesions or ulcerated plaquelike lesions on the extremities, sometimes centered on the digits or footpad.[48,49]

GI pythiosis in dogs is characterized by severe segmen-tal transmural thickening of the stomach, small intestine, colon, rectum, or (rarely) the esophagus or pharyngeal region (Figure 174-17).[50] Mesenteric lymphadenopathy is common and is occasionally observed without accompanying GI tract lesions. The gastric outflow area, duodenum, and ileocolic junction are the most frequently affected portions of the GI tract. Involvement of the mesenteric root may cause severe enlargement of mesenteric lymph nodes, which are often embedded in a single, large, firm granulomatous mass in the midabdominal region. Extension of disease into mesenteric vessels may result in bowel ischemia, infarction, perforation, or acute hemoabdomen. Clinical signs associated with GI pythiosis include weight loss, vomiting, diarrhea, and hematochezia. Physical examination often reveals a thin body condition and palpable abdominal mass. Signs of systemic illness are not typically present unless intestinal obstruction, infarction, or perforation occurs.

Laboratory abnormalities that may be associated with pythiosis include eosinophilia, anemia, and hyperglobulinemia. In dogs with GI pythiosis, abdominal radiographs usually reveal an abdominal mass or thickened segment of the GI tract. Ultrasonography typically demonstrates severe segmental thickening of the GI tract and mesenteric lymphadenopathy.

Figure 174-17 Cross-section of a segmental colonic lesion resected from a 3-yr old female Doberman with gastrointestinal (GI) pythiosis. The reader should note the thickening of the submucosa and narrowing of the colonic lumen.



174.2.6.3 Diagnosis

Histologically, pythiosis is characterized by eosinophilic pyogranulomatous inflammation. Although *P. insidiosum* hyphae are difficult to visualize on H&E-stained sections, they are easily identified in sections stained with GMS as broad (mean, 4 μ; range, 2 to 7 μ), rarely septate, occasionally branching structures. Because inflammation in GI pythiosis centers on the submucosal and muscular layers rather than mucosa and lamina propria, the diagnosis may be missed on endoscopic biopsies that fail to reach deeper tissues. Therefore pythiosis should be considered when endoscopic biopsies reveal eosinophilic or pyogranulomatous inflammation without identification of a causative agent.

Isolation of *P. insidiosum* from infected tissues is not difficult when appropriate sample handling and culture techniques are used. For best results, unrefrigerated tissue samples should be wrapped in a saline-moistened gauze sponge and shipped at ambient temperature to arrive at the laboratory within 24 hours. Identification of *P. insidiosum* should be based on morphologic features; growth at 37° C; production of motile, reniform,

biflagellate zoospores; and, if possible, specific PCR amplification or ribosomal RNA gene sequencing.[51] Although the production of zoospores is an important supporting feature for the identification of pathogenic oomycetes, it is not specific for *P. insidiosum*.

An ELISA for the detection of anti-*P. insidiosum* antibodies in dogs and cats has been found to be highly sensitive and specific for the diagnosis of pythiosis.[51] In addition to providing a means for early, noninvasive diagnosis, this assay also appears to be useful for monitoring response to therapy. Immunohistochemical techniques have previously been used to confirm the diagnosis of pythiosis. However, the specificity of these antibodies has not always been well established. A new polyclonal anti-*P. insidiosum* antibody raised in chickens and adsorbed with *Lagenidium* and *Conidiobolus* hyphae appears to be highly specific for the immunohistochemical detection of *P. insidiosum* hyphae in tissues.

687
688

174.2.6.4 Therapy

Aggressive surgical resection is the treatment of choice for pythiosis. When cutaneous lesions are limited to a single distal extremity, amputation is recommended. In animals with GI pythiosis, segmental lesions should be resected with 3 to 4 cm margins if possible. Unfortunately, most dogs with GI pythiosis are not presented until late in the course of disease, when complete excision is not possible. Local postoperative recurrence of pythiosis is common and can occur either at the site of resection or in regional lymph nodes. For this reason, medical therapy with a combination of itraconazole (10 mg/kg orally every 24 hours) and terbinafine (5 to 10 mg/kg orally every 24 hours) is recommended for at least 2 to 3 months after surgery. To monitor for recurrence, ELISA serology should be performed prior to and 2 to 3 months after surgery. In animals that have had a complete surgical resection and go on to have no recurrence of disease, serum antibody levels drop significantly within 3 months of surgery.[51] If this occurs, medical therapy can be discontinued, with subsequent reevaluation of serum antibody levels in 2 to 3 months.

Medical therapy for pythiosis is typically unrewarding, likely because ergosterol (the target for most currently available antifungal drugs) is generally lacking in the oomycete cell membrane. Despite this fact, clinical improvement has been documented in a small number of *P. insidiosum*–infected dogs treated with either itraconazole (10 mg/kg every 24 hours for 6 to 9 months) or ABLC (2 to 3 mg/kg administered three times weekly to a cumulative dose of 24 to 27 mg/kg). More recently, clinicians have observed clinical and serologic improvement or cure in several patients treated with a combination of itraconazole (10 mg/kg every 24 hours) with terbinafine (5 to 10 mg/kg every 24 hours). Although the percentage of animals responding is still poor (<20%), the combination protocol seems superior to itraconazole or amphotericin B alone.

174.2.7 Lagenidiosis

Until recently, *Pythium insidiosum* was considered to be the only mammalian pathogen in the class Oomycetes. However, in 1999, a second pathogenic oomycete was isolated from a dog with multifocal cutaneous lesions and regional lymphadenopathy. The dog died acutely after rupture of a caudal vena caval aneurysm, and necropsy revealed severe sublumbar lymphadenitis and pyogranulomatous vasculitis. Sequencing of a portion of the ribosomal RNA gene of the isolate recovered from this dog identified it as member of the genus *Lagenidium*.[52] Presently, more than 40 dogs with serologic, histologic, or culture evidence of *Lagenidium* spp. infection have been identified.

The majority of species in the genus *Lagenidium* are parasites of algae, fungi, nematodes, crustaceans, and insect larvae. The most well-studied species, *Lagenidium giganteum*, is a mosquito larval pathogen approved

for use as a biocontrol agent for mosquito populations. Although antigenic and molecular similarities suggest that the canine pathogenic *Lagenidium* species is closely related to *L. giganteum,* differences in their *in vitro* growth characteristics and the failure of *L. giganteum* to infect rodents in mammalian safety studies suggest that they are likely distinct species. Although little is currently known about the life cycle of the canine pathogenic *Lagenidium* species, it is likely similar to that of *P. insidiosum*.

174.2.7.1 Clinical Findings

The epidemiologic and clinicopathologic features of lagenidiosis are similar in many respects to those previously associated with cutaneous pythiosis. Affected animals are typically young to middle-aged dogs living in the Southeastern United States. Although most of these dogs have been from Florida or Louisiana, cases in Texas, Tennessee, Virginia, and Indiana have been identified as well. A number of infected dogs have had frequent exposure to lakes or ponds.

Dogs with *Lagenidium* spp. infection are typically presented for progressive cutaneous or subcutaneous lesions (often multifocal) involving the extremities, mammary region, perineum, or trunk.[52] Grossly, these lesions appear as firm dermal or subcutaneous nodules or as ulcerated, thickened areas with areas of necrosis and numerous draining tracts (Figure 174-18). Regional lymphadenopathy is often noted and may occur in the absence of cutaneous lesions. Similar to the clinical course associated with cutaneous pythiosis, skin lesions in dogs with lagenidiosis tend to be progressive, locally invasive, and poorly responsive to therapy. In contrast to pythiosis, however, the majority of dogs with lagenidiosis have been found to have lesions in distant sites, including great vessels, sublumbar and inguinal lymph nodes, lung, pulmonary hilus, and cranial mediastinum.

Figure 174-18 Ulcerative dermatitis caused by *Lagenidium* sp. infection in a 2-year-old female border collie presented for progressive skin lesions and generalized lymphadenopathy. This dog had similar lesions on all four limbs. The reader should note a large eschar distal to the ulcerative lesion.

174.2.7.2 Diagnosis

The histologic features of lagenidiosis are similar to those associated with pythiosis and zygomycosis and are characterized by pyogranulomatous and eosinophilic inflammation associated with broad, irregularly branching, sparsely septate hyphae. In contrast to *P. insidiosum*, *Lagenidium* spp. hyphae are usually visible on H&E-stained sections. On GMS-stained sections, numerous broad, thick-walled, irregularly septate hyphae are easily recognized. *Lagenidium* hyphae typically demonstrate a great deal of variability in size but in general are much larger than *P. insidiosum*, ranging from 7 to 25 μ in diameter, with an mean of 12 μ.

Immunoblot serology for the detection of anti-*Lagenidium* antibodies in canine serum can provide a presumptive diagnosis of lagenidiosis but must be interpreted in conjunction with results of serologic testing for *P. insidiosum* infection.[52] The definitive diagnosis of *Lagenidium* spp. infection is best made by culture. Because of current limitations associated with its morphologic characterization, definitive identification of *Lagenidium* spp. should be based on ribosomal RNA gene sequencing or specific PCR amplification.

174.2.7.3 Treatment

Aggressive surgical resection of infected tissues is the treatment of choice for lagenidiosis. In animals with lesions limited to a single distal extremity, amputation is recommended. Because dogs with lagenidiosis often have occult systemic lesions, radiographic imaging of the chest and abdomen and sonographic imaging of the abdomen is recommended to determine the extent of disease prior to attempting surgical resection of cutaneous lesions. Unfortunately, the vast majority of *Lagenidium*-infected dogs have nonresectable disease in regional lymph nodes or distant sites by the time the initial diagnosis is made. Medical therapy for lagenidiosis is typically ineffective, and in general, the prognosis for dogs with lagenidiosis is grave.

Table • 174-3 Drug Appendix

GENERIC	TRADE	DOSE	ROUTE	FREQUENCY
Amphotericin B	Fungizone	Dog: 0.22–0.5 mg/lb (0.5–1 mg/kg) Cat: 0.11–0.25 mg/lb (0.25–0.5 mg/kg)	IV	q48h
		Dog/cat: 0.22–0.36 mg/lb (0.5–0.8 mg/kg) diluted in 0.45% NaCl and 2.5% dextrose	SQ	q48h
Lipid amphotericin B complex (ABC)	Abelcet	Dog: 0.5–1.5 mg/lb (1–3 mg/kg)	IV	q48h
Flucytosine	Ancobon	Dog: 11.4–22.7 mg/lb (25–50 mg/kg)	PO	q6h
Ketoconazole	Nizoral	Dog: 4.5–13.6 mg/lb (10–30 mg/kg)	PO	q12h
Itraconazole	Sporanox	Dog: 2.2–4.5 mg/lb (5–10 mg/kg) Cat: 4.5 mg/lb (10 mg/kg)	PO	q24h
Fluconazole	Diflucan	Dog/cat: 1–4.5 mg/lb (2.5–10 mg/kg)	PO	q12h
Enilconazole		Dog: 4.5 mg/lb (10 mg/kg)	Intranasal	q12h
Clotrimazole	Lotrimin	Dog: 1 g	Intranasal	Once
Sodium iodide		Dog: 20 mg/lb (44 mg/kg) Cat: 10 mg/lb (22 mg/kg)	PO	q8
Terbinafine	Lamisil	Dog/cat: 4.5–9 mg/lb (10–20 mg/kg)	PO	q24h
Lufenuron	Program	Dog: 2.2–4.5 mg/lb (5–10 mg/kg)	PO	q24h

174.2.8 Zygomycosis

The term *zygomycosis* refers to infections caused by fungi in the class Zygomycetes, including the genera *Basidiobolus* and *Conidiobolus* in the order *Entomophthorales*, as well as the genera *Rhizopus, Absidia, Mucor*, *Saksenaea,* and others in the order *Mucorales*. Although infections caused by the *Mucorales* have not been well documented in small animals, the *Entomophthorales* have been reported in dogs to cause pyogranulomatous lesions that are grossly and histologically similar to those caused by *P. insidiosum* and *Lagenidium* spp. *Basidiobolus ranarum*, *Conidiobolus coronatus*, *Conidiobolus lamprauges,* and *Conidiobolus incongruus* are saprophytes found in soil and decaying plant matter. Cutaneous infection likely occurs by direct implantation of spores via minor trauma or insect bites. Systemic infection may result from inhalation or ingestion of spores. Affected animals are typically immunocompetent.

174.2.8.1 Clinical Findings

689

690

In humans and other mammals, conidiobolomycosis occurs most often as a nasopharyngeal infection with or without local dissemination into tissues of the face and retropharyngeal region. In two dogs evaluated in the authors' hospital, culture-confirmed conidiobolomycosis was associated with ulcerative lesions of the hard palate.[53] In two additional dogs, a presumptive diagnosis of nasopharyngeal conidiobolomycosis was made based on histologic and serologic findings. One of these dogs was presented for signs of chronic nasal cavity disease, and the other had a severe chronic ulcerative dermatitis of the nasal planum. In a fifth dog described in the literature, *Conidiobolus* infection was associated with multi-focal nodular draining subcutaneous lesions and regional lymphadenopathy.[54]

Basidiobolomycosis is a rare cause of ulcerative draining skin lesions in dogs and has also been reported in a single case as a cause of respiratory disease.[55] Disseminated *Basidiobolus* spp. infection involving the GI tract and other abdominal organs has been described in two dogs.

174.2.8.2 Diagnosis

The histologic features of zygomycosis are similar to those associated with pythiosis and lagenidiosis. On GMS-stained sections, hyphae appear broad, thin-walled, and occasionally septate. The histologic hallmark of entomophthoromycosis is the presence of a wide eosinophilic sleeve surrounding the hyphae. In general, hyphal diameter tends to be significantly larger for *Basidiobolus* spp. (mean, 9 μ; range, 5 to 20 μ) and *Conidiobolus* spp. (mean, 8 μ; range, 5 to 13 μ) than for *P. insidiosum* (mean, 4 μ; range, 2 to 7 μ).

The diagnosis of zygomycosis is based on isolation of the pathogen from infected tissues. Identification of zygomycetes in the laboratory is based on morphologic characteristics of asexual reproductive structures (conidia) and sexual reproductive structures (zygospores).

174.2.8.3 Treatment

Attempted therapy has only been described in a few patients with confirmed zygomycosis. Although anecdotal information and a small number of cases in the literature suggest that cutaneous entomophthoromycosis may be less aggressive than pythiosis or lagenidiosis, progression of cutaneous lesions and sometimes even dissemination despite treatment have also been described. Perhaps the most appropriate current recommendation for the treatment of entomophthoromycosis is aggressive surgical

resection of infected tissues whenever possible, followed by itraconazole therapy for 2 to 3 months. If resection is not possible, therapy with either itraconazole or ABLC should be recommended (Table 174-3).

175 CHAPTER • 175 Coccidioidomycosis and Aspergillosis

Autumn P. Davidson

175.1 INTRODUCTION

Unique among the continents, North America is host to three of the geographically defined major endemic mycoses: histoplasmosis, blastomycosis, and coccidioidomycosis. The three endemic pathogenic fungi share several characteristics. All are soil-dwelling organisms existing only within defined geographic regions based on specific environmental (soil and climatic) conditions. All are dimorphic, capable of undergoing morphologic change from a native saprophytic form (infectious to mammals; also found in vitro) to the parasitic form causing disease in vivo. *Histoplasma capsulatum* and *Blastomyces dermatitidis* convert in vivo into a "yeast form", and *Coccidioides immitis* converts to a "spherule." Infection in mammals occurs most commonly by inhalation of airborne spores. Inhaled saprophytic spores cannot be killed by neutrophils and are small enough (3 to 5 μm) to lodge in host alveoli. Recovery from infection depends on the competence of the host's cell-mediated immunity. Compromised cell-mediated immunity, due to chemotherapy for neoplasia, organ transplant, or immune mediated disease or as a consequence of immunocompromising viral infection, renders the host less able to resist colonization and dissemination of these fungi.[1]

Fungi and the infectious diseases they cause have become increasingly important in modern human and veterinary medicine, challenging mycologists to better understand their epidemiology, pathophysiology, and the host response. Popular current therapeutic targets include ergosterol in the fungal cell membrane and fungal RNA and DNA synthesis. Novel targets include enzymes involved in cell wall biosynthesis (1,3-beta glucan synthase and chitin synthase), as well as nonergosterol cell membrane molecules, DNA-related enzymes, intermediary fungal metabolism, and fungal virulence factors. Unfortunately, the prevalence of antifungal drug resistance appears to be increasing. Antifungal susceptibility testing is becoming more available and standardized. Data concerning combination therapy and sequential therapy as compared with single-agent therapy are accumulating. Adjunctive therapy with cytokines capable of immunohematologic modulation (granulocyte colony–stimulating factor [G-CSF], granulocyte macrophage colony–stimulating factor, macrophage colony–stimulating factor, and interferon-gamma) also have potential roles in the treatment and prevention of fungal infections. Stem cell and granulocyte transfusions and effective and safe vaccinations offer other avenues under development for restoration and improvement of host defense against mycotic disease.[2]

175.2 COCCIDIOIDOMYCOSIS

175.2.1 History and Mycology

Coccidioidomycosis ("valley fever," "valley rheumatism") was experimentally studied in dogs in the 1890s, but it was not described as a clinical entity in the veterinary literature until 1940. Coccidioidomycosis was recognized as a fatal granulomatous disease in humans during the late nineteenth century. Initially, the pathophysiology of coccidioidomycosis was thought to be neoplastic, a cancer induced by a protozoal organism because of the coccidial-like appearance of the spherule detected in biopsy specimens from affected individuals. Recognition of the mycotic cause of coccidioidomycosis and fulfillment of Koch's postulates occurred in 1900. *Coccidioides immitis* (within California) and *C. posadasii* (in all other endemic Southwestern regions) are the two pathogenic species causing coccidioidomycosis.[3–6]

The alkaline sandy soil environment characteristic of the lower Sonoran life zone in the southwestern United States, western Mexico, and Central and South America is the normal habitat for *Coccidioides* spp., which produce mycelia during seasonal rainfall. Arthroconidia (arthrospores) develop with soil drying, subsequently becoming airborne under appropriate environmental (dry and windy) conditions. In the dog and cat, inhalation of infectious and hardy arthroconidia is the major route of infection. Cutaneous contamination via a penetrating wound occurs less commonly. Experimentally, the canine infectious dose of inhaled arthroconidia is low (<10).[7]

175.2.2 Pathophysiology and Epizootiology

The severity and extent of clinical disease resulting from an infectious exposure depends upon the immunocompetence of the host, and ranges from a mild, clinically silent pulmonic form to fatal, multisystemic dissemination. *C. immitis* transforms in tissue to its parasitic form, the spherule, which undergoes internal division (endosporulation) and ruptures at maturity. Each endospore can become an endosporulating spherule, promoting continuation and expansion of the parasitic phase (Figure 175-1). Spherules or endospores can revert to the mycelial form of growth under appropriate environmental conditions, such as might be found under bandages covering a draining tract. As such, the disease is not believed to be directly contagious among mammals except by direct innoculation of infectious body fluids (blood, semen). Pulmonary infection is characterized by extension from the bronchioles and alveoli, through peribronchiolar tissues, to the subpleura and the tracheobronchial and mediastinal lymph nodes. Dissemination is defined as spread of coccidioidal infection beyond the tracheobronchial and mediastinal lymph nodes. Disseminated disease most commonly involves the axial and appendicular skeleton and overlying skin, abdominal viscera, central nervous system (CNS) (including the eye), pericardium, myocardium, and the prostate gland (Figures 175-2 and 175-3).[8]

The incidence of coccidioidomycosis is increased in young, male, medium to large breed outdoor dogs. The boxer, pointer, Australian shepherd, beagle, and Scottish terrier were found to have increased incidence in one study, although it is not believed that pure breed dogs are generally at greater risk than mixed breed dogs. A breed-specific susceptibility based in host immunocompetence may exist.[9]

Figure 175-1 *Coccidioides immitis* endosporulating spherule.

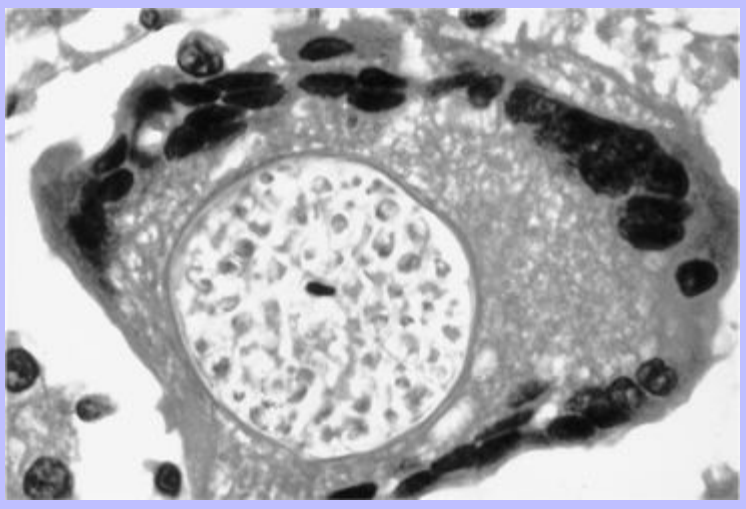

Figure 175-2 Prescapular lymphadenopathy secondary to disseminated coccidioidomycosis in a dog.

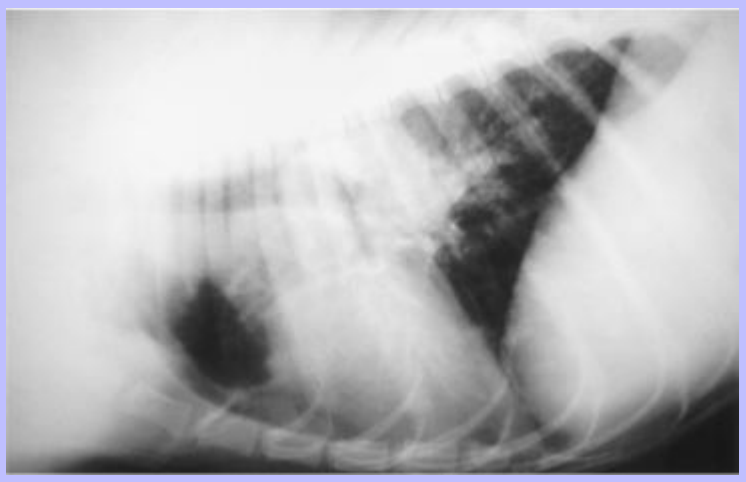
175.2.3 Diagnosis

The diagnosis of coccidioidomycosis should be first based on clinical signs compatible with the infection (most commonly cough, lethargy, anorexia, fever, chronic lameness, cervical or head pain, and weight loss) and positive serologic findings. Early in the course of disease (2 to 5 weeks), a positive precipitin test reflects increased IgM levels. Subsequent (8 to 10 weeks) positive complement fixation (CF) testing marks the presence of IgG antibodies. Canine anticomplementary factors can interfere with CF testing, making quantitative immunodiffusion with concentration techniques more reliable than CF. Persistence or reappearance of a positive precipitin test can indicate dissemination. Early CF titers of greater magnitude may suggest more likelihood of dissemination. CF titers may persist at low levels (1:4) during recuperation. Negative serology in an infected individual reflects fulminating disease or anergy.[2,10]

Figure 175-3 Osseous coccidioidomycosis, dissemination to the carpi of a dog.

Figure 175-4 Marked sternal and tracheobronchial (perihilar) lymphadenopathy caused by pulmonary coccidioidomycosis in a dog.



Radiographic changes occurring with coccidioidomycosis are well described. Pulmonary lesions vary in character and severity. Most commonly, peribronchiolar and interstitial nodular lesions are associated with hilar lymphadenopathy (Figures 175-4 and 175-5). Skeletal lesions also vary, productive lesions are more common than lytic lesions, and both may be present simultaneously (Figures 175-6 and 175-7). Characteristic laboratory changes associated with coccidioidomycosis include a mature neutrophilic leukocytosis, mild anemia, monocytosis, hyperglobulinemia, and hypoalbuminemia. Histopathology, mycology, and cytology can also enable a positive diagnosis of coccidioidomycosis but are more invasive (biopsy), are hazardous to laboratory personnel (culture), and are less sensitive (cytology) than serology. A specific and sensitive polymerase chain reaction (PCR) assay for detection of *Coccidioides immitis* DNA is anticipated to assist with earlier diagnoses and subtle cases.[11–13]

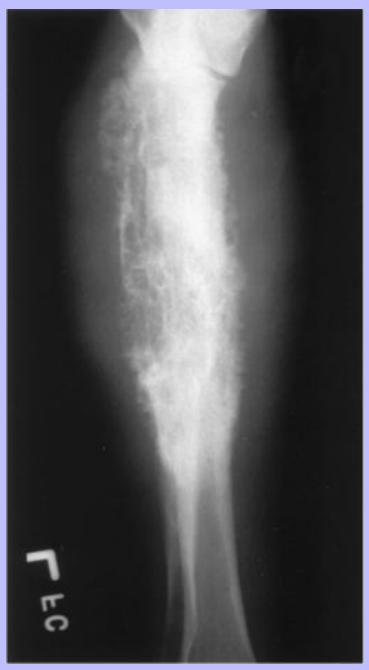
Figure 175-5 Nodular pulmonary infiltrates caused by pulmonary coccidioidomycosis in a dog.

Figure 175-6 Disseminated coccidioidomycosis with vertebral (L3) spondylitis in a dog.

Coccidioidomycosis is a reportable disease in humans and considered a serious biohazard due to the highly infectious nature of the saprophytic phase (present in laboratory cultures and the soil). One half to two thirds of humans with primary coccidioidal pulmonic infection are subclinical and resolve their disease and then have durable cellular immunity. The intradermal skin test has been used in humans to identify individuals with such immunity. The outcome of infection in humans is highly correlated with patient profiling (age, sex, race, and reproductive status). The elderly, young, dark-skinned races, and women in the third trimester of pregnancy are at increased risk of serious infection. Five to 10% of primary pulmonary infections in humans result in pulmonary sequelae (nodules or cavities), and only 0.5% to 1.0% progress to chronic pulmonary infection or significant extrapulmonary dissemination. Humans with primary uncomplicated respiratory coccidioidomycosis usually resolve their infection without specific therapy, and it is not believed that therapy adds significant benefit. Pulmonary sequelae may not cause symptoms but warrant close clinical monitoring for evidence of progression to extrapulmonary infection. Treatment of dogs showing clinical signs of pulmonary coccidioidomycosis has traditionally been encouraged and is thought to reduce the potential for dissemination that results in a poorer prognosis. It is not known how many dogs in endemic areas recover from occult, clinically inapparent pulmonary infection with coccidioidomycosis. Epizootiologic studies evaluating serologic evidence of previous infection are underway in parts of the endemic area. A 20% rate of exposure adequate to cause seroconversion is apparent. The intradermal skin test is not reliable in the dog. The incidence of actual illness resulting from *Coccidioides* infection in animals living within endemic areas is not known. Treatment of symptomatic cats is supported by the fact that disseminated disease is already likely present once the diagnosis is made. Weight loss and cutaneous lesions (chronic draining tracts) are the most commonly reported symptoms in the cat. A lack of familiarity with the disease in nonendemic areas may hamper diagnosis in dogs and cats having traveled through endemic regions.[13,14]

692
693

Figure 175-7 Disseminated coccidioidomycosis with radial and ulnar osteomyelitis in a dog.



175.2.4 Therapy

Therapy of coccidioidomycosis has involved both amphotericin B (standard and novel lipid formulations) and the azoles (ketoconazole, itraconazole or fluconazole) as sole agents, in combination, or in succession. Numerous clinical reports exist in the veterinary literature regarding therapy for coccidioidomycosis, with variable recommendations for length of treatment based on the assessment of clinical cure. Treatment for a minimum of 4 to 6 months beyond clinical cure, with marked reduction or resolution of positive serologic findings, is advised. Relapse reportedly occurs commonly and it is not known if resolution of disease in the dog and cat results in lifelong immunity as is believed in humans. Humans living in endemic areas and undergoing immunosuppressive therapy associated with organ transplant experience a 3% (approximate) infection rate. If past exposure to coccidioidomycosis can be documented pretransplant, concurrent antifungal and immunosuppressive therapy is given. Immunosuppression-induced recrudescence of disease in a dog after occult infection has recently been reported.[16]

The soil organism *Streptomyces nodosus* is the source of the gold standard antimycotic agent amphotericin B. Amphotericin B is a polyene antibiotic with antifungal activity due to binding ergosterol, a sterol moiety in the fungal cell membrane, forming channels that increase the permeability of the membrane. Amphotericin B is both fungistatic and fungicidal, depending on the concentration of the drug and the sensitivity of the fungal organism. It is not absorbed to any large extent through the skin or across mucous membranes. Amphotericin B (Fungizone) was introduced in the 1950s and was the first effective parenteral drug available for the treatment of invasive mycoses. Amphotericin B has the widest spectrum of activity of the clinically available antifungal agents. Its major limitation is its narrow therapeutic window. Amphotericin B is administered as an intravenous or intrathecal agent, usually every 48 hours. The intravenous dose, given in 5% dextrose, is 0.25 (feline) to 0.5 (canine) mg/kg intravenously Q 48 hr to a final dose of 5 to 10 mg/kg. The intrathecal dose is up to 0.5 mg in 3 to 5 mL spinal fluid, three times weekly. Amphotericin B is cumulatively nephrotoxic and its use is limited by associated azotemia). Phlebitis, chills, fever, anorexia, renal tubular acidosis, hypokalemia, hypomagnesemia, anemia, thrombocytopenia, leukopenia, and anaphylaxis are other side effects associated with its use. Slow intravenous infusions and pretreatment saline diuresis reduce nephrotoxicity. Recent reports suggest success using amphotericin B subcutaneously diluted in large volumes of saline (0.5 mg/kg in 400 ml 0.45% saline, given every 2 to 3 days to a cumulative dose of 10 to 20 mg/kg). The original formulation of amphotericin B is a micellar suspension with sodium deoxycholate. Recently, novel preparations of amphotericin B in lipid and liposomal-based formulations have been developed that are significantly less nephrotoxic but more costly. Slightly higher doses of these lipid formulations are required for efficacy equal to Fungizone, but the higher doses are well tolerated. Nephrotoxicity is still possible with lipid formulations, and infusional reactions remain a complication. Amphotericin B lipid complex (ABLC) (Abelcet) is dosed at 1 mg/kg intravenously Q 48 hr to a total dose of 12 mg/kg. ABLC and amphotericin B in colloidal dispersion (ABCD) are other lipid formulations. Amphotericin is recommended for serious disseminated coccidioidal infections.

Azole agents for treating mycotic infections were developed during the 1980s and 1990s. Miconazole and clotrimazole were early azoles intended for topical use (see Aspergillosis, Therapy). Ketoconazole (Nizoral), an imidazole, was the first oral agent with an acceptable performance against the endemic mycoses and permitted outpatient therapy. The development of the triazoles, itraconazole (Sporanox) and fluconazole (Diflucan), followed. Azoles are usually fungistatic, inhibiting ergosterol synthesis from lanosterol by interacting with C-14 alpha demethylase, an enzyme dependent on cytochrome P-450. The result is increased cell membrane permeability and inhibition of fungal cell growth. At high concentrations achievable topically, some azoles may be fungicidal due to direct damage to fungal cell wall components (disturbed membrane lipid organization resulting in cell lysis). Other antifungal actions of the azoles include inhibition of endogenous respiration,

toxicity to membrane phospholipids, and inhibition of the transformation of yeasts to their mycelial form. The interaction with cytochrome P-450 enzyme systems causes some of the side effects in mammals associated primarily with ketoconazole. Inhibition of adrenal and gonadal steroid synthesis can occur with ketoconazole administration. Ketoconazole, itraconazole, and fluconazole are available as oral preparations (pill form). Itraconazole and fluconazole are also available as parenteral preparations. Itraconazole has recently become available as an oral solution and a novel intravenous formulation, both in a beta cyclodextrin carrier that vastly improves absorption and bioavailability, allowing higher concentrations in affected tissues. Ketoconazole and itraconazole undergo hepatic metabolism and can be associated with hepatotoxicity, gastrointestinal (GI) intolerance, and cutaneous reactions. Fluconazole is excreted largely unchanged through the kidneys, is well absorbed orally, and has good CNS penetration. With increased prophylactic and long-term use of the azoles, fungal resistance is emerging, especially in immunocompromised humans on extended periods of therapy. The recommended dose of ketoconazole (brand name or its newly available generic equivalent) is 5 to 15 mg/kg orally every 12 hours (given with food). The recommended dose for itraconazole is 5 mg/kg orally (given with food) or intravenously every 12 to 24 hours, and for fluconazole it is 2.5 to 5.0 mg/kg orally or intravenously every 24 hours.

693

694

Currently, ketoconazole therapy, although expensive by veterinary standards, is less cost prohibitive than the expense of hospitalization, supportive care, and renal monitoring required by the appropriately conservative use of amphotericin B. In addition, it is less costly than the later generation azoles, itraconazole, and fluconazole. Amphotericin B therapy in rapidly progressing, serious fungal infection should be followed by long-term oral azole therapy. The use of amphotericin should thus probably be reserved for refractory, disseminated, or fulminating cases. The increased cost of itraconazole and fluconazole may be offset by the suspected, but not yet well-documented, increased efficacy in animals. The improved bioavailability of itraconazole solution supports its use in serious or refractory disease. Fluconazole is indicated for animals with CNS involvement. The use of liposomal amphotericin will permit higher doses to be administered for longer periods of time with less nephrotoxicity. Voriconazole (Pfizer) is a newly approved azole being used in humans with refractory fungal infection. It has excellent oral absorption and favorable pharmacokinetics. Little data are available on its use in coccidioidomycosis.[2,17,18]

Chitin makes up a higher percentage of the fungal cell wall when the organism is in a mycelial phase. Nikkomycin Z, discovered in the 1970s and currently undergoing development, is a natural chitin synthase inhibitor, resembling the precursor substrate. Nikkomycin Z holds great promise as a fungicidal agent, also exhibiting marked in vitro synergism with the azoles.

Lufenuron, a benzoylphenyl urea, is a nonspecific insect chitin synthase inhibitor used in veterinary medicine to sterilize female fleas. Anecdotal clinical reports suggested that lufenuron was useful against coccidioidal infection. Controlled studies have subsequently shown no apparent efficacy or synergy of the compound as an antifungal agent in vitro or in vivo.[19–21]

175.3 ASPERGILLOSIS

175.3.1 Mycology and Epizootiology

Aspergillus species are filamentous fungi that are ubiquitous under appropriate environmental conditions and not typically infectious due to host resistance (Figure 175-8). Aspergillosis in humans is typically a pulmonary hypersensitivity reaction rather than an infectious disease entity, except in immunocompromised individuals where disseminated infection with *Aspergillus* species is problematic. Pets acquire infectious aspergillosis in two forms: (1) localized (usually sinonasal) and (2) disseminated (involving two or more noncontiguous

organs), both more common in the dog than cat. Aspergillus species typically proliferate by producing spores in vegetative decaying soil and water (Figure 175-9).

Figure 175-8 Methenamine-silver stain of histologic section of *Aspergillus* spp. showing characteristic parallel septate hyphae with acute angle branching.

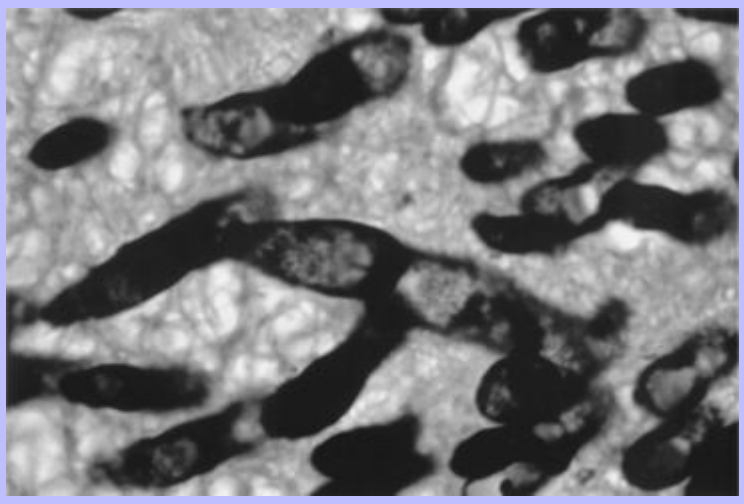


Figure 175-9 *Aspergillus flavus* in culture showing conidiophores bearing fruiting heads.

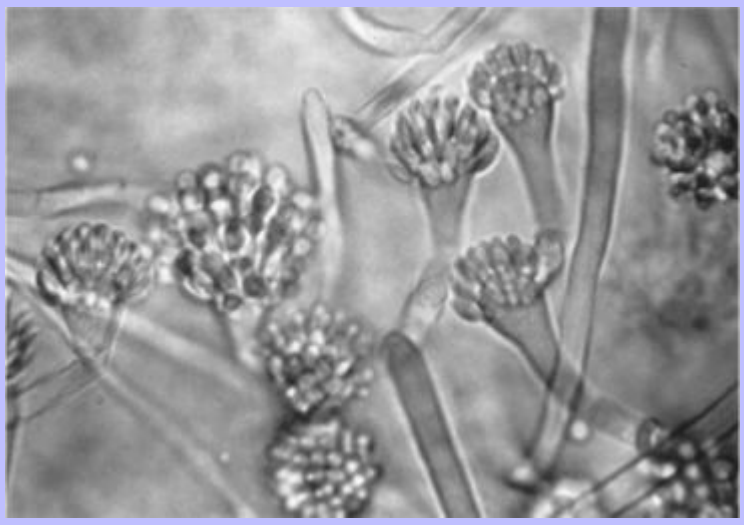

175.3.2 Localized (Sinonasal) Aspergillosis

Canine sinonasal aspergillosis is characterized by colonization and invasion of the nasal passages and frontal sinuses by the saprophytic fungus, *Aspergillus fumigatus*. *A. fumigatus* is regarded as an opportunistic pathogen, suggesting that some pre-existing local nasal mucosal immunocompetence allowed its establishment in the upper respiratory tract. Alternatively, an in vitro inhibition of B and T lymphocyte transformation by *A. fumigatus* products has been described, suggesting that immunosuppression may both result from or be perpetuated by infection. Sinonasal aspergillosis may occur as an opportunistic primary infection or it may occur secondary to the presence of a foreign body (foxtail, splinter), nasal trauma, or neoplasia (Figure 175-10). The primary form of the disease most commonly affects young to middle-aged mesaticephalic and dolichocephalic breeds and is progressive unless effective specific therapy is given. German shepherds and Rottweilers are the breeds more commonly affected.[22,23]

694

695

Figure 175-10 Foxtail removed from the nasal passage of a dog with sinonasal aspergillosis.

175.3.3 Pathophysiology

Colonization and invasion of the nasal mucosa by *A. fumigatus* results in destruction and necrosis of the nasal turbinates, often accompanied by frontal sinus osteomyelitis. The cribriform plate, palatine bones, and orbit are sometimes involved. Facial pain, anorexia, sneezing, and copious mucoid to hemorrhagic nasal discharge and crusting are common clinical signs (Figure 175-11). Life-threatening epistaxis can occur secondary to erosion of the nasal vasculature. With chronicity, depigmentation and ulceration of the nares and masticatory muscle atrophy result (Figures 175-12 and 175-13). CNS involvement (encephalitis, meningitis) precipitating seizures can result after erosion of the cribriform plate.

175.3.4 Diagnosis

The condition should be differentiated from other inflammatory causes of rhinitis such as infestation with nasal mites, idiopathic lymphocytic-plasmacytic rhinitis, bacterial or other mycotic rhinitis, chronic nasal foreign body, and nasal neoplasia. The diagnosis of sinonasal aspergillosis is best made by direct observation and microscopic demonstration of invasive fungal plaques on the nasal mucosa (Figure 175-14). Culture of *A. fumigatus* from affected tissues is supportive of the diagnosis, but fungi can contaminate nasal mucosa diseased from other causes. It is a good rule to suspect neoplasia as the primary condition in older dogs with confirmed aspergillosis. Serologic evaluation of sinonasal aspergillosis is unreliable, both false-positive and false-negative results occur. Additionally, serology is not prognostic in aspergillosis. Biopsy of affected tissue and histopathologic evaluation for mucosal invasion is confirmatory.[24]

Radiology of the nasal passages and frontal sinuses (radiography and computed tomography [CT]) is useful in the diagnosis of sinonasal aspergillosis but must be performed before rhinoscopic evaluation to avoid artifacts resulting from lavage, tissue manipulation, and hemorrhage. Radiography shows loss of fine nasal turbinate detail and fluid density in the nasal passages and frequently the frontal sinuses (Figure 175-15). In advanced cases, an aspergilloma may exist in the frontal sinus (Figure 175-16). CT evaluation is useful because characteristic lesions may be identified and evaluation of the extent of disease is optimized. CT has provided a new appreciation for the aggressive nature of fungal rhinitis. Mild cases of sinonasal aspergillosis result in relatively little structural change within the nasal cavity other than the regional lysis of nasal turbinates. Dogs that are chronically infected often demonstrate dramatic turbinate destruction, gross epithelial thickening, formation of dense fungal colonies and granulomas, and penetration into adjacent bone causing hyperostosis and in some instances gross bony destruction. Dogs with sinonasal aspergillosis frequently have copious, thick nasal exudate obscuring radiographic identification of granulomas. Administration of intranasal iodinated contrast medium can help define mass lesions in the presence of surrounding fluid.[24–26]

Figure 175-11 Severe crusting of nasal planum and nares in a dog with sinonasal aspergillosis.

Figure 175-12 Ulceration and depigmentation of the nares of a dog with chronic sinonasal aspergillosis.

Numerous techniques have been described to obtain tissue specimens for the definitive histopathologic diagnosis of sinonasal aspergillosis. General anesthesia is usually required, with a cuffed endotracheal tube placed to prevent aspiration of blood and lavage fluids. The external surface of the nasal cavity is visually and digitally examined for evidence of swelling, asymmetry, and ulceration. This includes a thorough oral examination and visualization of the nasopharynx with either a flexible fiber-optic scope or an angled, warmed dental mirror. Placement of precounted gauze sponges in the pharynx, for further protection of the airways, is then performed. Larger laparotomy sponges should be used if possible because these are less easily swallowed by dogs that may react to manipulation of sensitive nasal tissues. The clinician should then measure the distance from the nares to the area of interest noted on the nasal radiographs or CT. This distance serves as a guide for obtaining nasal biopsy and culture specimens. In addition, prior to inserting any instrument in the nasal cavity, the distance from the nares to the medial canthus of the ipsilateral eye is noted and should not be exceeded or penetration of the cribriform plate may result (Figure 175-17). Rhinoscopy should be performed while the animal is in sternal recumbency. Only a limited examination of the rostral nasal cavity can be performed with an otoscope. A rigid arthroscope with a 1.9 to 2.7 mm outside diameter and a 5 to 25 degree angle of view (Richard Wolf Medical Instruments Corp., 7046 Lyndon Avenue, Rosemont, IL 60018) permits a more comprehensive evaluation of the nasal passages. A flexible bronchoscope with a 3.5 to 4.8-mm outside diameter (Olympus Corporation, 4 Nevada Drive, Lake Success, NY 11042-1179) has the added benefit of allowing visualization of the nasopharynx by retroflexing the scope around the soft palate, but it is more difficult to manipulate through the nasal passages. Light resistance is usually felt while inserting the scope through the nares. The scope can then be directed ventrally into the ventral nasal meatus toward the nasopharynx or dorsally into the dorsal nasal meatus toward the olfactory epithelium, openings (ostia) of the frontal sinuses, and the cribriform plate. The advantages of direct visualization of the nasal cavity are that a more thorough understanding of the nature of the disease process might be obtained and placement of a biopsy instrument at the area of interest is facilitated.

695

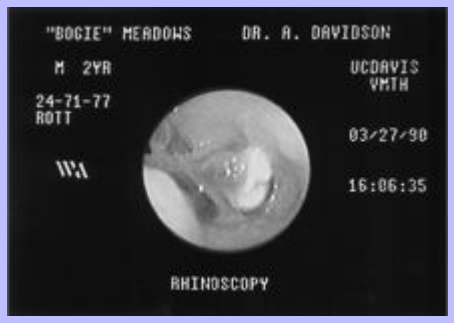

Figure 175-15 Nasal radiography showing loss of turbinate detail and fluid density associated with nasal aspergillosis in a dog.

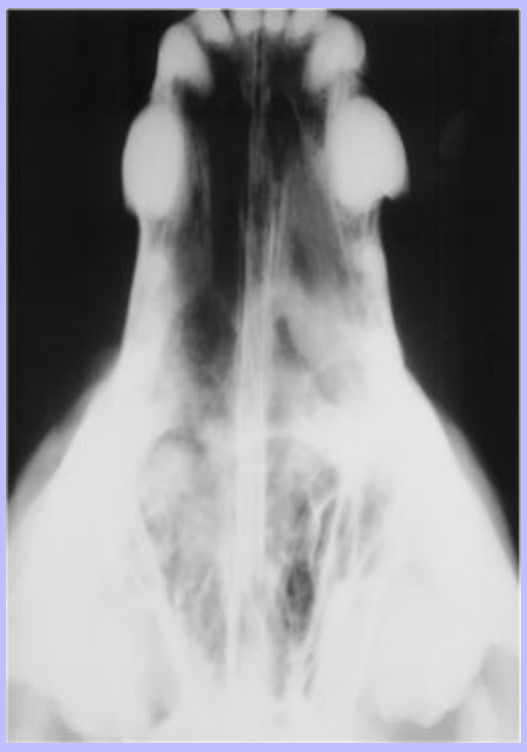

Figure 175-16 Aspergilloma in the frontal sinus of a dog.

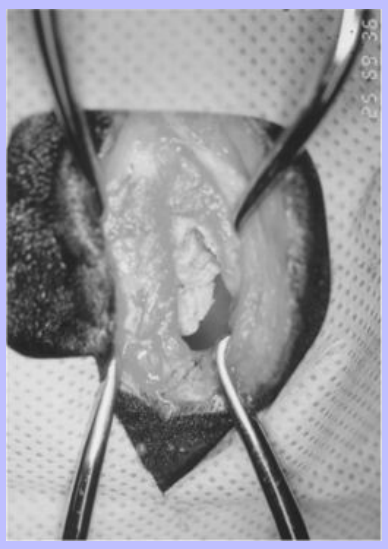


Indirect methods of obtaining tissue specimens via the nares have also been described. As with rhinoscopic examination, prebiopsy imaging studies are recommended. Biopsy instruments should never be inserted beyond the level of the ipsilateral medial canthus, and protection of the airways under general anesthesia is recommended. The simplest of these techniques involve flushing the nasal cavity with saline in an attempt to dislodge diagnostic tissue. A catheter should be placed in the nares, or retroflexed 180 degrees around the soft palate. Gauze sponges are used to catch tissues that are flushed out through the nares or into the pharynx. More aggressive blind techniques include flushing the nasal cavity while reaming the area of interest with a stiff plastic tube or biopsy with a biopsy needle (Tru-Cut® Disposable Biopsy Needle; Travenol Laboratories Inc., Morton Grove, IL 60053), a plastic catheter, or by applying suction to a Foley urethral catheter. These techniques do not allow the characterization of the disease process that is possible with direct visualization and 696
may result in nondiagnostic or misleading tissue samples. However, they do not require specialized equipment, 697
are easy to perform, and may result in a definitive diagnosis. If the cytologic diagnosis is inconsistent with the signalment, history, or imaging studies, the clinician should repeat the procedure or consider one that allows direct visualization of the area of interest.[24]

Figure 175-17 Marking the distance from the rostral nares to the ipsilateral medial canthus before rhinoscopic evaluation.

175.3.5 Therapy

Therapeutic recommendations for sinonasal aspergillosis have included surgery and systemic and topical antimycotic medications. Rhinotomy and turbinectomy with perioperative thiabendazole administration resulted in improvement in 50% or less of dogs in one study. Oral ketoconazole administration was reportedly efficacious in 47%, oral itraconazole in 60% to 70%, and oral fluconazole in 60% of infected dogs. Enilconazole applied topically through frontal sinus tubes (twice daily for 7 to 10 days) was reportedly efficacious in 80% to 90% of dogs but is cumbersome and not readily available in the United States. Extensive débridement of the nasal cavities and frontal sinuses followed by infusion of 1% to 2% enilconazole via endoscopically placed catheters has been advocated. Invasive surgical exposure of the nasal passages and

frontal sinuses, topical application of 10% povidone iodine, and delayed closure 6 to 8 weeks postoperatively was recommended for refractory cases but had poor client acceptance and a small study size.[22]

Clotrimazole is a synthetic imidazole derivative. At concentrations achieved during systemic use, imidazoles impair the biosynthesis of ergosterol, the major component of fungal cell membranes, resulting in interference with certain membrane-bound enzyme systems and fungistatic inhibition of growth. In addition, clotrimazole is fungicidal topically, reaching higher concentrations (1.5×10^{-4}M). Electron microscopic observations indicate that at high concentrations, clotrimazole causes alteration in the fungal cell membrane with consequent changes in permeability and leakage of cellular constituents in a manner similar to the effect of polyene antifungal antibiotics. This drug is available in human topical preparations for cutaneous, oral or vaginal applications. Administered orally, it is poorly absorbed and rapidly absorbed undergoes hepatic metabolism and biliary excretion. GI irritation and contact hypersensitivity are reported human side effects.[23,27]

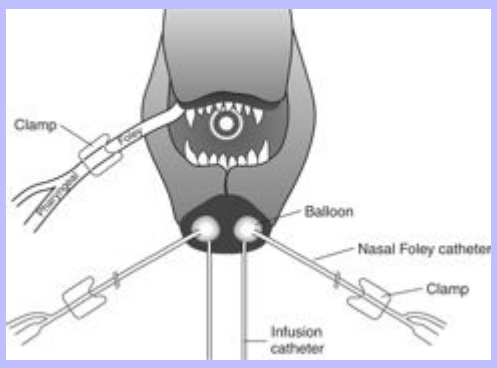
Clotrimazole solution has been used successfully for the topical treatment of nasal aspergillosis in the dog. The topical delivery of clotrimazole has been accomplished using two techniques. In the first, an infusion of clotrimazole is delivered through infant feeding tubes placed into the frontal sinuses and caudal nasal passages through the skull (a somewhat invasive procedure requiring surgical expertise for trephination and tube placement). An alternative technique, based on studies of the distribution of topical agents in the frontal sinuses and nasal passages, involves the retrograde infusion of clotrimazole through polypropylene catheters placed into the nares. This technique is equally successful, technically simpler, and associated with less morbidity. Based on a previous study in cadavers, the average volume of the frontal sinuses in breeds predisposed to fungal rhinitis is 25 mL per side. Flooding the nasal cavity and sinuses with a larger volume of infusate (50 to 60 mL per side) results in distribution to all areas of the nasal cavity and frontal sinuses. Delivery by trephination and feeding tube placement can bypass areas within the frontal sinuses. At present, the recommendation is to use 50 to 60 mL per side in middle to large breed dogs, regardless of head size.

Catheters should be placed with the dog in lateral recumbency. A 24 F Foley catheter is placed per os so that the tip of the catheter lays dorsal to the soft palate. This process can be aided initially by grasping the catheter tip with a pair of right-angle forceps (Meeker) or long-handled needle holders so that the catheter tip is directed rostrally. A mouth gag is then placed, and an assistant should retract the tongue rostrally to improve visualization during catheter placement. The catheter can then be advanced until its balloon is dorsal to the junction of the hard and soft palates. The balloon of the Foley catheter is then inflated to occlude the nasopharynx. The balloon can be palpated through the soft palate to confirm its position just caudal to the hard palate. Moistened laparotomy sponges should be counted and then placed in the pharynx so that the catheter cannot migrate caudally and will absorb any infusate that might escape around the balloon. During sponge placement the index finger of the opposite hand is used to maintain balloon position. Once this process is complete, the mouth gag is removed. One 10 F polypropylene infusion catheter is then advanced through each nostril, beginning dorsomedially; each is advanced into the dorsal nasal meatus to the level of the medial canthus of the ipsilateral palpebral fissure. A Foley catheter (12 F) is then inserted into each nostril and the balloons inflated so that they lay just caudal to and occluding the nostrils. Occasionally a nylon suture is placed across each nostril to prevent cranial migration of the nasal balloons. After three Foley catheters (one nasopharyngeal, two nasal) are placed, and their balloons should be inflated to slow the leakage of clotrimazole from the nasal cavity and frontal sinuses (Figures 175-18 and 175-19). The dog is then repositioned in dorsal recumbency, and an additional laparotomy sponge is placed just caudal to the upper incisors (between the endotracheal tube and the incisive papilla) to absorb leakage of clotrimazole through the incisive ducts.

Clotrimazole (1 g) in 100 mL of polyethylene glycol 200 (a 1% solution) is then evenly divided between two 60 mL syringes (50 mL per syringe). Initially the nasal passages and frontal sinuses must be filled with solution.

When clotrimazole is noted within the lumen of a Foley catheter it should be clamped shut, eventually creating a closed system for saturation of the nasal and frontal sinus mucosa. The clotrimazole should then be continuously and slowly infused over a 1-hour period (50 mL per infusion catheter). The polypropylene catheters are maintained in a horizontal position, parallel to the table, throughout infusion. Positioning the dog so that its nose protrudes beyond the edge of the treatment table allows clotrimazole escaping around the nasal catheters to drip into a receptacle. While the dog's body is maintained in dorsal recumbency, the head can be tilted and maintained in the following positions to ensure drug contact with all mucosal surfaces: dorsal 697
recumbency (15 minutes), left lateral recumbency (15 minutes), right lateral recumbency (15 minutes), and 698
dorsal recumbency (15 minutes). The dog is then placed in sternal recumbency, the catheters and sponges removed and counted, the clotrimazole allowed to drain rostrally, and the pharynx and proximal esophagus suctioned before recovery from anesthesia.

Figure 175-18 Catheter position with the dog in dorsal recumbency. A Foley catheter with the balloon inflated in the nasopharynx and pharyngeal gauze sponges (not shown) minimize leakage of infusion caudally. A cuffed endotracheal tube *(et)* further diminishes the risk of aspiration. Syringes (60 mL) are used to inject infusion into the dorsal nasal meatus via polypropylene infusion catheters. Inflated Foley catheter balloons obstruct the nares to diminish leakage of infusion rostrally. Tubing clamps on Foley catheters are closed when fluid is observed within the catheter lumen. (Adapted from Mathews KF et al: Computed tomographic assessment of noninvasive intranasal infusions in dogs with fungal rhinitis, *Vet Surg* 25:309, 1996.)



Topical administration of clotrimazole into the frontal sinuses and nasal passages is generally well tolerated. Pharyngitis, conjunctivitis, and pharyngeal edema have been reported as transient side effects. The success rate with one or more topical clotrimazole applications has been reported to be 86%. The infection will resolve in most dogs after a single treatment. A favorable response to clotrimazole therapy is usually indicated by resolution of nasal discharge by 2 weeks after therapy. Unabated persistence of nasal discharge 2 weeks after therapy is an indication for repeat evaluation and treatment if aspergillosis persists. Concurrent systemic antibiotic therapy may be indicated if secondary bacterial rhinitis is present. Some dogs with advanced disease may require multiple 1-hour clotrimazole infusions. Cases selected for topical therapy should have aspergillosis

limited to the frontal sinuses and nasal passages, without CNS involvement. Pretreatment CT scans are encouraged so that the extent of the disease is determined and the integrity of the cribriform plate evaluated. Remember, however, that no test (including CT scan) is 100% reliable in determining if the cribiform is intact. 698
Informed consent should be obtained from clients. Topical infusion of clotrimazole solution is not advised if the 699
cribriform plate is not intact, because serious meningitis and encephalitis may result. Cases with CNS involvement, characterized by a lack of integrity of the cribriform plate or orbit (ocular or retrobulbar involvement), should receive systemic antifungal therapy (preferably fluconazole). Only the formulation of clotrimazole in polyethylene glycol is advised. The use of clotrimazole in propylene glycol-isopropyl alcohol vehicles is problematic due to the tendency of the latter to significantly irritate oronasal mucosa. Topical therapy with itraconazole oral suspension in refractory cases is currently under clinical investigation.[28–30]

175.3.6 Disseminated Aspergillosis

Disseminated aspergillosis is most commonly diagnosed in dogs and cats that are terminally ill from the disease. Disseminated aspergillosis typically involves multiple organ systems with no history of nasal or pulmonary involvement. *Aspergillus terreus*, *A. deflectus*, *A. flavipes,* and rarely *A. fumigatus* have been reported in cases where the species has been identified. Disseminated aspergillosis is believed to occur after inhalation of small spores (<8 μm) and hematogenous spread. The pathogenicity of the causative species is reported to be associated with their production of highly infective aleuriospores in tissue and their inherent ability to invade blood vessels. In dogs, disseminated aspergillosis has been most commonly reported in the German shepherd between 2 and 8 years of age. Genetic predisposition and dysfunctional mucosal immunity are suspected. Defective IgA production or regulation has been identified in some affected German shepherds.

Cats with disseminated aspergillosis generally have identifiable concurrent immunosuppressive disease (usually viral) or other debilitation and are less than 2 years of age.

The clinical signs associated with disseminated aspergillosis are nonspecific and related to organ involvement. Uveitis, enophthalmitis, and chorioretinitis may precede the onset of generalized disease. Osteomyelitis and mycotic granulomas of the kidneys, liver, spleen, intervertebral discs, pancreas, lymph nodes, myocardium, prostate, brain, uterus, and thyroid gland have been reported. Bone pain, paraparesis, draining sinus tracts, anorexia, weight loss, pyrexia, lethargy, muscle wasting, and fever are the most common signs. Animals with disseminated aspergillosis may have fungal hyphae observed on cytologic examination of urine sediment, serum, synovial fluid, lymph node centesis, bone biopsy, or intervertebral disc aspiration. The diagnosis is confirmed by culture on Sabouraud's dextrose agar. Serology is not reliable (false negatives have been reported).

The prognosis for recovery is poor despite aggressive antifungal therapy and supportive care. Intravenous amphotericin B, itraconazole, or fluconazole are advised initially. Long-term (sometimes for life) oral azole therapy can be attempted if an initial positive response to intravenous antimycotic drug administration occurs. Surgical excision of fungal granulomas may be helpful, if feasible.[31–33]

176 CHAPTER • 176 Tropical Diseases

Remo Lobetti

In the past, the term *tropical diseases* referred to diseases that occurred only in the tropic regions of the world. However, the distinction between tropical and nontropical disease is becoming increasingly blurred, and diseases that traditionally were considered tropical now occur in many nontropical places. Moreover, some of the parasitic infections formerly thought to be uncommon or very localized are now recognized to have a wide distribution. Possible reasons for the expansion of tropical diseases to other parts of the world include global warming, especially with diseases that are vector borne, and the ever-increasing movement of both people and animals, which allows dissemination and spread of disease. The presence of tropical diseases is compounded by socioeconomic factors, pet-owner relationships, and nutritional disorders. Diseases that may still be considered of a tropical nature are listed in Table 176-1.

176.1 AFRICAN HORSE SICKNESS

African horse sickness is caused by a double-strand RNA orbivirus. In addition to equines, the dog is the only other species that can contract African horse sickness.[1] Dogs usually contract the disease by ingesting infected horsemeat, but they can also become infected through vector-borne transmission by *Culicoides* midges.[2] Typical clinical signs include fever, cough, and diarrhea, and the disease progression is often acute. Postmortem examination demonstrates severe pulmonary edema, pleural effusion, and splenomegaly.[1] Antibodies to African horse sickness have been detected in healthy dogs from Egypt, India, and South Africa.[2] No specific therapy is available for the disease.

176.2 FLAVIVIRIDAE

Flaviviridae are vector-borne, single-strand RNA viruses.[3] Of all the viruses in this group, the two that are of a tropical nature and that affect the dog and cat are yellow fever and Wesselsbron disease.

Yellow fever, which is transmitted by *Aedes* mosquitoes, produces a subclinical infection in cats that is characterized by a transient viremia, whereas dogs are resistant to the virus.[4] Affected cats may show a transient febrile reaction. Wesselsbron disease has been reported in a dog that died from encephalitis. When three dogs were challenged with the viral isolate from the succumbed dog, two showed a transient febrile reaction and one developed transient paresis.[5] Antibodies to Wesselsbron disease have been detected in healthy dogs from Botswana and South Africa.[5] The diagnosis is usually made retrospectively on postmortem examination. No specific therapy is available for the disease.

Table • 176-1 Diseases That May Still Be Considered of a Tropical Nature

ORGANISMS	DISEASE
Viruses	Orbivirus (African horse sickness)
	Wesselsbron disease
	Yellow fever
	Rift Valley fever
Bacteria	Melioidosis
	Anthrax
Protozoa	Southern African canine babesiosis
	Feline babesiosis
	Trypanosomiases
	Sarcocystosis
Ectoparasites	*Hyalomma* tick bite necrosis
	Cordylobia infestation
Endoparasites	Spirocercosis

It is likely that transient, nonspecific signs of encephalitis in dogs and cats may in fact be the result of infection with Flaviviridae.

176.3 BUNYAVIRIDAE

Bunyaviridae, the largest family of vector-borne, single-strand RNA viruses, includes many important pathogens of both humans and animals.[6] Of all the viruses in this group, the only one of a tropical nature is Rift Valley fever. The *Aedes* mosquito is the most common vector, although midges, ticks, and sand flies also can transmit the infection. Direct trans-mission, by inhalation or ingestion, from affected animals is also possible.[6] In young puppies and kittens, infection with Rift Valley fever virus results in viremia, hepatic and myocardial necrosis, meningitis, diffuse petechial hemorrhages, and death.[4] Although adult animals do not succumb to the infection, they can develop a viremic state, and infection in a pregnant animal can result in abortion or stillbirths.[4,6] The diagnosis is usually made retrospectively on postmortem examination. No specific therapy is available for the disease.

176.4 MELIOIDOSIS

Melioidosis is a bacterial infection caused by *Burkholderia (Pseudomonas) pseudomallei*. The disease occurs in Southeast Asia, northern Australia, and the South Pacific. The organism is a ubiquitous soil saprophyte that results in chronic nodular or purulent generalized systemic inflammatory disease in dogs, cats, and other species.[7] The route of infection is by inhalation, ingestion, or direct transmission into wounds or tissues by bites of arthropod vectors or by direct contact with contaminated soil.[7,8] Isolation of the organism from blood or lesions is diagnostic. Therapy is aimed at surgical drainage of large abscesses and long-term systemic antibiotic therapy.[8]

176.5 ANTHRAX

Anthrax is an acute bacterial systemic disease of mammals caused by *Bacillus anthracis*. In dogs and cats the infection is rare and is manifested by local inflammation, necrosis, and edema of tissues of the upper gastrointestinal tract, which first come into contact with the organism.[9] Although death is usually by asphyxiation,

the toxin can also exert systemic effects. The cat and dog are usually infected by the ingestion of meat from contaminated carcasses of animals that have died from anthrax.[9,10] The diagnosis is made by detection of the bacillus on a blood or edema fluid smear. Postmortem examination is not recommended, because this results in dissemination of the bacterial spores.[10] Treatment is with penicillin antibiotics.[10]

176.6 CANINE BABESIOSIS

Canine babesiosis is an important worldwide, tick-borne disease that ranges in severity from relatively mild to fatal. The causative organism is either *Babesia canis* or *Babesia gibsoni*. Three subtypes of *B. canis* are recognized: *B. canis canis, B. canis vogeli,* and *B. canis rossi*. The first two subtypes occur in Europe and North Africa, respectively, and the third subtype occurs in Southern Africa.[11] *B. gibsoni* occurs in Asia, North America, and North and East Africa.[12] *B. canis canis, B. canis vogeli,* and *B. gibsoni* all result in mild clinical disease; *B. canis rossi* results in severe clinical disease and is the focus of this section.

Canine babesiosis may be clinically classified as uncomplicated and complicated forms.[13] Uncomplicated cases typically present with signs relating to acute hemolysis, including fever, anorexia, depression, pale mucous membranes, splenomegaly, and a waterhammer pulse. This form is further characterized as mild, moderate, or severe disease, according to the severity of the anemia.

With the complicated form of babesiosis, clinical manifestations include acute renal failure, neurologic dysfunction, coagulopathies, liver dysfunction, acute respiratory distress syndrome, myocarditis, hypotension, and pancreatitis. Rare complications include myalgia, ocular involvement, upper respiratory signs, necrosis of the extremities, and fluid accumulation.[14]

Primary hematologic abnormalities include anemia, thrombocytopenia, and leukocytosis. Alterations in biochemical parameters vary, depending on the severity of the case. Typically, uncomplicated cases may show no biochemical changes. However, increased liver enzyme activities, hypokalemia in more severely affected cases, and an increased blood urea nitrogen (BUN) with a normal serum creatinine may be evident. In complicated cases, biochemical changes reflect the underlying complication.[14]

The diagnosis of babesiosis is made by demonstrating *Babesia* organisms (2 × 5 μm, pear-shaped organisms, usually in pairs) in infected erythrocytes on a blood smear stained with a Romanowsky-type stain.

The primary therapeutic aim in the treatment of babesiosis is the reversal of life-threatening anemia through blood transfusions and elimination or suppression of the parasite with specific antibabesial drugs, such as diminazene aceturate and imidocarb. Mild to moderate, uncomplicated cases require only antibabesial therapy; severe uncomplicated cases require antibabesial therapy and blood transfusions. The complicated forms of the disease require additional therapy aimed at treating the complication present.[14]

176.7 FELINE BABESIOSIS

Feline babesiosis is caused by *Babesia felis*, a small *Babesia* parasite that has been reported from France, Germany, Thailand, and Zimbabwe but that only appears to cause clinical disease in South Africa.[15] 700 701

Common clinical signs include anorexia, weight loss, and anemia. Less common signs may include icterus, vomiting, pica, and respiratory signs. The disease can be protracted and often is clinically silent until fairly far advanced. Anemia is the most consistent hematologic finding; white cell and thrombocyte counts are variable and

inconsistent. The most remarkable changes on serum biochemistry are increased alanine aminotransferase (ALT) activity and hyperbilirubinuria. Other biochemical parameters are generally variable and inconsistent.[15] The diagnosis of babesiosis is made by demonstrating *Babesia* organisms in infected erythrocytes on a blood smear stained with a Romanowsky-type stain.

The drug of choice for treating feline babesiosis is the antimalarial drug primaquine phosphate, given at a dosage of 1 mg per cat every 36 hours for four treatments, then 1 mg per cat per os every 7 days for four treatments. The drug does not sterilize the infection. Another drug that reportedly has some effect is doxycycline, given at a dosage of 5 mg/kg per os twice a day for 21 days.[16]

176.8 AFRICAN TRYPANOSOMIASES

Trypanosomiasis is a hemoparasitic protozoal disease that in the dog is caused either by *Trypanosoma brucei* or *Trypanosoma congolense*.[17] The disease is transmitted by the tsetse fly, although dogs may become infected by eating infected fresh meat.[18]

Relapsing fever, anemia, weakness, anorexia, and emaciation are common clinical signs. Other clinical signs include anasarca, conjunctivitis, keratitis, and occasionally neurologic signs (depression, incoordination, circling, and paralysis).[18] In untreated cases, death may occur in 1 week to 3 months.

The diagnosis is made by direct visualization of parasites on blood smear evaluation. Indirect fluorescent antibody (FA) and enzyme-linked immunosorbent assay (ELISA) methods and species-specific monoclonal antibodies can also be used in the diagnosis.[19] Hematologic changes include regenerative anemia, leukopenia, and thrombocytopenia.[17]

Few drugs are effective against African trypanosomiases; however, drugs that have been used include diminazine (most effective), difluoromethylornithine, ethidium, isometamidium, and quinapyramin.[17,18]

176.9 SARCOCYSTOSIS

Sarcocystosis is a protozoal disease caused by organisms of the genus *Sarcocystis*.[20] The dog and cat are definitive hosts, and cattle, sheep, and pigs are intermediate hosts. When a dog or cat ingests meat containing sarcocysts, bradyzoites develop into macrogametocytes and microgametocytes in the epithelial and goblet cells of the intestine. Oocysts then form, which sporulate in situ within the intestinal wall; they are released into the intestinal lumen, where they leave the host via the feces. Sarcocystosis in the dog and cat is usually asymptomatic, but acute to chronic diarrhea may occur.

In the dog and cat the diagnosis is made by finding the small sporocysts in the feces using a supersaturated sodium chloride solution. Potentiated sulfonamides can be used in the dog and cat to eliminate the intestinal infection.[20]

176.10 *HYALOMMA* TICK BITE NECROSIS

Skin necrosis induced by the bite of the *Hyalomma* tick is a common disease of southern Africa. Dermatrophic skin necrosis is thought to be caused by a cytotoxin produced in the salivary gland of the tick.[21] The initial stage the disease is characterized by severe pain at the site of the tick attachment. This is followed by erythema and

edema at the site of the tick bite. Full-thickness skin necrosis follows. The size of the necrotic area, which can vary from 5 to 30 cm, appears to be directly related to the length of time the tick was attached.

The diagnosis is based on clinical signs and the presence of one or more *Hyalomma* ticks. Treatment involves removal of the tick and general principles of wound management.

176.11 *CORDYLOBIA ANTHROPOPHAGA*

The larvae of the *tumbu* or mango fly *(Cordylobia anthropophaga)* produce myiasis in humans and animals in sub-Saharan Africa. The adult fly deposits the eggs on skin that usually is soiled with urine or feces. Within 2 days the larvae hatch and penetrate the skin to form a furuncular lesion with a small central opening. The larvae are obligate parasites and usually provoke a localized furuncle, but aberrant migrating larvae may result in necrotic and inflammatory lesions in many tissues.[23{22}] The larave pupate after 8 or 9 nine days, and the whole life cycle can be completed in less than 4 weeks.[22{23}]

Therapy includes mechanical removal of the larvae, covering the breathing hole in the skin with petroleum jelly, or the use of systemic ivermectin drugs. Prevention involves grooming, good hygiene, and the use of topical insecticidal shampoos and repellants.

176.12 SPIROCERCOSIS

Spirocerca lupi is a nematode parasite of carnivores found primarily in dogs but that also can occur in numerous wild carnivores.[24] Spirocercosis occurs throughout the world, having a tropical and subtropical distribution, although some colder regions have a high incidence.[24,25] Infection depends on the canine population density and the degree of contact between definitive, intermediate, and transport hosts.[24] The adult parasite is most commonly found embedded in a nodule in the host's thoracic esophagus, although it can occur in other parts of the body.[25] In the esophagus the adult worm passes larvated eggs into the lumen; these hatch only after being ingested by an intermediate host (coprophagous beetles).[24,25] Transport hosts (birds, amphibians, reptiles, and small mammals) can become infected if they ingest the intermediate host.[24]

The definitive host becomes infected by ingestion of the intermediate or the transport host. Once ingested, the larvae are liberated in the stomach. From there they penetrate the stomach wall, enter an arteriole, and migrate in the wall of the gastric and gastric-epiploic arteries to the celiac artery and then to the thoracic aorta. From the aorta, the larvae emerge and migrate to the adjacent esophagus. This process takes approximately 6 months.[24,25] The pathology of spirocercosis results from larval migration, the presence of adult worms in granulomas in the esophagus, and secondary bacterial infections.[24] In some cases, the esophageal granuloma can undergo malignant transformation to form a sarcoma, with and without metastases.[26]

Clinical signs of spirocercosis include vomiting, regurgitation, weight loss, salivation, and dysphagia.[24,27] Aortic infection is asymptomatic unless rupture occurs, in which case hemo-thorax and sudden death may occur. The diagnosis is based on survey and contrast radiographs, esophagoscopy, and the finding of larvated eggs on fecal flotation.[24,25,27] The larvated eggs are not a common finding, however, because the adult female can shed eggs only if an opening exists in the granuloma; also, the eggs are shed only for an unpredictable short period.[24] Because the eggs are heavier than other helminth eggs, a flotation fluid of higher specific gravity is required. Doramectin has been shown to be effective in the therapy of spirocercosis.[28]

701 702

It has been speculated that in endemic areas, the incidence of spirocercosis infection may be 100%, a rate probably associated with the many opportunities for acquiring infection from the various intermediate and transport hosts.

177 CHAPTER • 177 Public Health Aspects of Small Animal Practice

Leonard C. Marcus

Veterinarians must protect clients, staff, and the general public from diseases acquired from animals. This chapter reviews prevention and control of zoonoses in small animal practice. The diagnosis and treatment of these diseases in animals are discussed elsewhere in this text.

177.1 BITE-AND SCRATCH-RELATED INFECTIONS

Animal bites and scratches can range from trivial and self-healing to severely mutilating or fatal. Rabies is the most feared consequence of an animal bite. Almost all cases of dog rabies and all cases of cat rabies in the United States and Canada are acquired from wildlife. The last focus of enzootic domestic canine rabies is along the U.S. -Mexican border, and the disease there is being brought under control. Because dogs and cats remain an important bridge of infection between wildlife and humans, veterinarians should vigorously support animal control legislation and mandatory rabies immunizations for dogs and cats.

All veterinary clinical staff in the United States and Canada (except Hawaii, which is rabies free) should be immunized against rabies before exposure.[1] A vaccine grown on human diploid cells (Imovax; Aventis Pasteur, Swiftwater, PA) or on chick embryo cells (RabAvert; Chiron Corp., Emeryville, CA) is currently available. Both are inactivated. They are given on days 0, 7, and 21 or 28.

Anyone exposed to rabies after completing the pre-exposure series should be given two booster immunizations 3 days apart. Anyone who was not previously immunized should be given one weight-based dose of rabies immune globulin (RIG), with as much as possible infiltrated into the area of the bite or scratch; also, rabies vaccine should be given on days 0, 3, 7, 14, and 28. RIG should not be given to anyone who had pre-exposure immunization. Rabies vaccine should be given to adults in the deltoid muscle, not in the buttocks, to avoid injection into fat rather than muscle. Intradermal vaccine is not available in the United States at this time.

After completion of the pre-exposure series, veterinary staff should have titers checked every 2 years, and a booster should be given if the indirect fluorescent focus inhibition test (IFFIT) result drops below a titer of 1:5 or 0.5 IU/mL.

Testing for antibody before administration of a rabies booster is advisable to reduce adverse side effects, which are more common with boosters than with the primary series. It is also cost-effective, because most individuals maintain an adequate titer for many years, and the cost of testing is much lower than that of immunization.

In addition to transmission through bites or scratches, rabies can be transmitted through contact of saliva, cerebrospinal fluid (CSF), or infected tissue with a mucous membrane or opening in the skin. Possible veterinary occupational exposures include being cut with a surgical or necropsy instrument, using bare hands while performing an oropharyngeal examination, or being sprayed in the eyes or mouth with saliva during a dental procedure or with CSF while decapitating an animal or performing a spinal tap. The use of gloves, masks, and goggles reduces risk. Areas exposed to infective material should be cleaned thoroughly; soap and water should be used for cutaneous exposure, and flushing or rinsing with water should be done for ocular and oral exposures. Contact with blood, urine, or feces is not considered an exposure risk.

Bacterial infections associated with dog and cat bites include *Pasteurella multocida, Pasteurella canis, Staphylococcus* and *Streptococcus* species, plague, tularemia, and *Capnocytophaga canimorsus*.[2] Bite wounds should be washed immediately with soap and water to reduce the risk of infection. Bite victims should be advised to consult a physician about further treatment. Tetanus boosters, rabies immunizations, suturing, or prophylactic antibiotics may be indicated, depending on the circumstance, location, and condition of the wound, the likely pathogen, and the underlying health status of the individual.

Bartonella henselae causes several human ailments, the most common in immunocompetent people being cat scratch disease. Other forms of infection (e.g., bacillary angiomatosis, peliosis hepatis, endocarditis, and retinitis) occur mostly in immunocompromised individuals, such as those with acquired immunodeficiency syndrome (AIDS).[3]

B. henselae is usually transmitted to humans through a scratch from a cat. Cats are infected by interfeline fights and by fleas *(Ctenocephalides felis)*. Fleas may possibly infect humans as well. Transmission can be reduced by eliminating fleas and avoiding actions that are likely to result in a bite or scratch, such as teasing a cat with a short string.

The occupational risk of bites and scratches can be reduced through proper animal restraint, including the use of protective gloves, muzzles, and tranquilizers. Staff, not clients, should handle animals in the veterinary office. Signs to that effect (available from the American Veterinary Medical Association [AVMA] Professional Liability Insurance Trust) should be on display. Clients should be educated about bite prevention, including selection of appropriate pets and avoiding situations that result in bites, especially with small children. The AVMA has brochures for clients on these topics. Aggressive animals should receive behavior modification therapy.

177.2 FECAL-ORAL TRANSMITTED INFECTIONS

Animal feces are an important source of human disease. *Salmonella, Campylobacter, Giardia,* and *Cryptosporidium* spp. are major fecal pathogens with a wide host range, including cats and dogs.

Most cases of human giardiasis and cryptosporidiosis are transmitted person to person. When pets and humans are infected in the same household, it usually cannot be determined if all were infected through a common or different source or if the humans acquired the infection from the animals (or vice versa). Animals can be infected by drinking from toilet bowls, a practice that should be discouraged. Although differences in strains exist, all feline and canine cases of salmonellosis, campylobacteriosis, giardiasis, and cryptosporidiosis should be considered potentially zoonotic.[4]

Toxoplasma gondii has an indirect life cycle, with felids as the only definitive host. Although humans can be infected transplacentally, by organ transplant, or by ingestion of oocysts in soil or cysts in meat, traced back far enough, all human cases ultimately have a feline source.[5]

Most cats acquire toxoplasmosis within the first year of life. The patent period is only 1 to 2 weeks. Infection usually induces protective immunity, with little likelihood of much additional shedding of oocysts. Therefore the proba-bility of finding *Toxoplasma* oocysts in randomly collected feline feces is small and has little public health value. Serologic testing for toxoplasmosis may be useful to diagnose clinical disease in the cat. It has little value in public health, except (if negative) to exclude a particular cat as the source of human toxoplasmosis.

Hydatid disease is infection with the larval stage of *Echinococcus* tapeworms, usually *E. granulosus* or *E. multilocularis*. The space-occupying lesions cause severe disease in humans; *E. multilocularis* is frequently fatal.[6,7] Infection is acquired through ingestion of eggs passed in animal feces.

Veterinarians should know the geographic distribution of adult *Echinococcus* infections and should screen definitive host species for these infections if they come from enzootic areas. *E. granulosus* is an adult tapeworm in the small intestine of wild and domestic canids. It is found in sheep dogs and, less commonly, other dogs in some western states. It is also found in canids from parts of Canada, South America, Europe, the Middle East, Africa, and Australia.

E. multilocularis is found in wild and domestic canids and domestic cats in Canada, the north-central United States, northern and central Europe, and parts of the Middle East and Asia. It may have been introduced into the U.S. southern states with the importation of foxes from Canada for hunting.

Visceral and ocular cases of larva migrans are most commonly caused by the larvae of *Toxocara canis* and less commonly by *Toxocara cati* or *Baylisascaris procyonis*.[6,7] Humans become infected by ingesting embryonated eggs. Cutaneous larva migrans, or *creeping eruption,* is usually caused by the larvae of cat and dog hookworms; infection occurs through skin contact with contaminated soil.[6,7] The pinworm *(Enterobius vermicularis)* is host specific for humans and is never acquired from dogs or cats.

Because of the long external incubation period (which averages 2 weeks), transmission of ascarids and hookworms in a veterinary hospital is unlikely. *Salmonella, Campylobacter, Giardia, Cryptosporidium,* and *Echinococcus* species are infective at the time of passage and can be transmitted in veterinary hospitals. *Toxoplasma* oocysts have an external incubation period of 2 to 3 days, therefore daily disposal of feline feces should eliminate the risk of transmission.

Prevention of fecally transmitted diseases requires education of clients and staff in hygiene and sanitation. Hands should be washed with soap and water or alcohol skin cleaners after animals, cages, or fecally contaminated equipment has been handled, even if gloves were worn.[8] Feces should be flushed down toilets or incinerated. Veterinarians should promote “pooper scooper” laws to reduce the risk of fecally transmitted diseases in public areas. Personnel that clean cages and kennels should wear protective masks and eyewear to avoid ricocheting water from high-pressure hoses. Two-inch wide slides are safer than the standard 1-inch slide for microscopic fecal examinations. Sealing the edges of cover slips with Permount or nail polish further increases safety. Gloves should be worn to clean cages or handle fecal specimens in the laboratory. Tools used for cage cleaning should be disinfected between cages to reduce nosocomial and zoonotic infections.

Fecally soiled surfaces should be decontaminated using approved disinfectants. Steam or flaming may be needed to kill ascarid eggs.

Prophylactic deworming schedules should be followed to reduce the infection of dogs and cats with ascarids, hookworms, and *Echinococcus* organisms.[7] Treatment for other parasites and pathogenic bacteria should be given if they are diagnosed by stool examination or culture. However, antibiotic treatment of intestinal *Salmonella* infection usually is contraindicated because of the risk of the development of antibiotic resistance.

Intestinal infections can be reduced by feeding cooked, canned, or dry food and by preventing predatory behavior by cats and dogs (e.g., keeping cats indoors).

177.2.1 Cutaneous Zoonoses

Various infections can be transmitted by direct contact between an animal and human skin. Several species of ringworm are zoonotic, the most common being *Microsporum canis*. Sporotrichosis is a fungal infection usually acquired by inoculation of spores in soil or organic matter. Transmission by contact with feline lesions has occurred in rare instances.

Parasitic mites vary considerably in host specificity. *Notoedres cati* very rarely infects humans; *Sarcoptes scabiei* var. *canis* does occasionally, usually transiently; *Cheyletiella* spp. readily bite humans but do not remain on them, therefore the diagnosis is made by finding mites on contact animals. Dermanyssid mites thrive in the nests of birds and rodents and bite the animals while they are nesting. These mites also bite humans, but diagnosis and control may depend on finding the nesting site.

Ctenocephalides felis and *C. canis* commonly bite humans, but their life cycle depends on the use of cats and dogs as preferred hosts. *C. felis* transmits *B. henselae* to cats and possibly to humans. *C. felis* and *C. canis* are intermediate hosts for *Dipylidium caninum,* a tapeworm that rarely infects humans because transmission requires ingestion of the flea. Because there is no approved (human) medical treatment for fleas in the United States, the animal hosts and their environment must be treated.[9] Lice are host specific. Pediculosis in humans is transmitted person to person, not from animals.

Dogs and cats that hunt can acquire fleas from prey (e.g., rodents) and bring them home. The fleas can bite humans and transmit infections such as plague and murine typhus. Dogs and cats can also bring ticks into a house. If the ticks are unattached, they could transfer to a person, but humans usually acquire ticks outdoors.

Zoonotic skin disease can be reduced through prompt diagnosis and treatment of animals, disinfection or removal of fomites, and adequate hand washing.

177.2.2 Zoonoses Associated with Animal Genitourinary Products

Leptospirosis is acquired through contact with infected animal urine. Dogs are commonly infected, cats rarely are. The disease can vary from mild to severe or fatal in humans. Occupational risk can be reduced by ensuring that personnel wear gloves, a mask, and goggles while cleaning cages or handling urine specimens in the laboratory, by disinfecting exposed surfaces, and by washing the hands. Exposure would appear to be high in veterinary facilities, but reported cases are rare among veterinary staff in the United States. In a high-risk situation, a single dose of doxycycline (200 mg given orally) is prophylactic.[10]

703

704

Q fever, caused by *Coxiella burnetii,* is usually transmitted by aerosol or by ticks. The source of infection often is the products of conception. Individuals who assist in obstetrical delivery of animals are at risk. Although most infections are associated with cattle, sheep, and goats, dogs and cats also harbor the organism.[11]

Brucella canis is rarely transmitted to people by contact with canine genital secretions or products of conception or abortion.

177.2.3 Zoonoses Associated with Respiratory Infections in Animals

The worst respiratory infection of cats and dogs directly transmissible to humans by aerosol is plague, which is enzootic in the western United States and parts of Asia, Africa, and South America. Suspected human or animal

cases should be reported immediately to the appropriate health agencies and confirmatory diagnostic procedures done. Suspect and proven cases and their contacts (human and animal) must be quarantined and treated. Veterinarians have contracted fatal pneumonic plague from cats.[12]

Bordetella bronchiseptica is a rare cause of human disease. “Strep throat” in humans is caused by *Streptococcus pyogenes*. It is transmitted person to person, and rarely, if ever, by an animal. Animals often carry other, non-group A streptococci in their oropharynx or skin. Definitive diagnosis of *S. pyogenes* requires Lancefield group serotyping.

Dogs and cats rarely get *Mycobacterium tuberculosis*. It is more often transmitted from humans to pets than vice versa, therefore the human source should be traced and treated.

Systemic mycoses, such as histoplasmosis, coccidioidomycosis, and blastomycosis, are transmitted by contact with or inhalation of spores from the soil. They can cause pulmonary, cutaneous, or multiorgan infection in humans and animals. Finding these infections in animals indicates an environmental source to which humans may be exposed.

177.2.4 Zoonoses in Immunocompromised People, Pregnant Women, and Children

Individuals with AIDS or some forms of leukemia, those who are undergoing chemotherapy or corticosteroid or other immunosuppressive therapy for cancer, autoimmune disease, arthritis, or organ transplant, or those who have congenital immunodeficiency are uniquely susceptible to opportunistic infections. Many of these are zoonoses (e.g., cryptosporidiosis, toxoplasmosis, salmonellosis, and bartonellosis). Asplenia increases the risk for potentially fatal sepsis with *C. canimorsus* and babesiosis.

If a woman acquires toxoplasmosis during pregnancy, the fetus could become infected and suffer severe congenital defects. Infection in the woman before conception provides protective immunity for the fetus, therefore antibody screening could provide assurance (if positive) that future pregnancies are not at risk.

It is inappropriate for veterinarians to delve into a client's health status, because such inquiry could be interpreted as practicing human medicine.[13] However, if a person volunteers the information that he or she is immunocompromised, it is appropriate for the veterinarian to advise the person to be especially careful to avoid zoonotic diseases.[14,15] If an opportunistic zoonosis is diagnosed in an animal, the owner can be advised in an open-ended way that the organism can infect humans and could cause severe illness in pregnant or immunocompromised individuals.

Because of their behavior, ignorance of risk, and poor sanitary habits, children are more at risk than adults of being injured or infected by animals. Special efforts should be made to educate parents of young children about the prevention of zoonoses and injuries from animals.

177.3 GENERAL PRINCIPLES OF VETERINARY PUBLIC HEALTH

Animals often carry *Salmonella, Campylobacter, Giardia, Cryptosporidium, Toxoplasma, Echinococcus,* and roundworms in the intestine asymptomatically. They also can harbor ringworm without dermatitis and can shed *Leptospira* organisms in the urine and appear well. Therefore the practice of putting warning signs on cages and applying precautions only with sick animals ignores the risk from subclinical carriers.

Hands should be washed after animals or items contaminated by their excretions have been handled. Veterinary staff should wash hands between each patient. Items soiled by urine or feces should be disposed of in a sanitary manner. Food should not be stored in refrigerators used to hold laboratory specimens. Veterinary hospitals should have effective isolation rooms and procedures for animals with contagious diseases, including the use of antiseptic footwear baths, eyewear, disposable booties, gowns, gloves, and masks; and safe sharps disposal.

Clients and staff should be educated about disease prevention, and this information should be reinforced with pamphlets and written protocols. Posting signs about washing hands, no smoking zones, and safe food storage helps. Written guidelines can cover specific situations, such as who will feed and handle rabies suspects and the way in which feces will be handled in the laboratory.

People seeking to reduce zoonotic risks when acquiring a pet can be advised to get a healthy-appearing, mature animal from a known source with no recent history of fleas, diarrhea, or respiratory or cutaneous disease. Pets should be immunized and dewormed according to standard protocols and examined regularly (e.g., annually as adults). Pets with diarrhea, cough, dermatitis, or fever should be evaluated and treated definitively and promptly.

Veterinarians should interact constructively with physicians, educating them about the transmission of zoonoses but avoiding litigious risk of involvement with individual patient care. Consultation between knowledgeable veterinarians and physicians is mutually beneficial.

177.4 BIOTERRORISM

Most potential agents of germ warfare directed against humans are zoonoses (e.g., anthrax, brucellosis, glanders, plague, Q fever, tularemia, viral encephalitides, and viral hemorrhagic fevers). Some of these occur naturally in dogs and cats, others do not, but genetic manipulation could change the host range of pathogens. It is possible that animals could become a persistent reservoir of infection after an initial attack. Veterinarians should promptly report unusual presentations or patterns of disease suggestive of bioterrorism to appropriate government authorities.

177.5 MEDICAL-LEGAL ASPECTS OF VETERINARY PUBLIC HEALTH[13]

Veterinarians can be sued if their malpractice results in human injury or zoonotic disease. Damages can include medical expenses, lost wages, and pain and suffering. Malpractice includes failure to diagnose a zoonotic disease, treat it properly, or warn potential human contacts of the risk of transmission. The veterinary record should include the advice given to clients and others in potential contact with the animal (e.g., ways to reduce exposure and to seek medical care). Records should be kept of injuries and disease exposures that occur among staff and the response to those incidents.

704 705

Veterinarians should not offer (human) medical advice or treat human patients. The only exception might be immediate first aid that would reasonably be expected of any lay person (e.g., washing a bite or scratch wound or applying pressure to reduce bleeding from an injury inflicted by an animal).

Reportable diseases must be reported. Criminal as well as civil consequences can ensue if damages occur because of failure to report.

177.6 SUMMARY AND CONCLUSION

The great majority of zoonoses are preventable through education of clients, staff, and the general public, as well as sanitation and treatment of animal carriers. Veterinarians are obligated to incorporate public health measures into their practice. Even with these precautions, the benefits of pet ownership far outweigh the risks.

178 CHAPTER • 178 Principles of Chemotherapy

Angela E. Frimberger

178.1 INTRODUCTION

Chemotherapy is the principal modality used to treat systemic cancers such as hematologic malignancies and metastatic solid tumors. In managing chemotherapy, communication between the veterinarian and the owner is essential, and it must be frank and compassionate. All options should be presented to the owner without regard to the clinician's preconceptions of the owner's preferences. The goal of chemotherapy in human oncology is usually to cure the patient; however, in veterinary medicine, palliation is often a more appropriate goal. It is important to determine the goal of treatment at the outset because it often determines the course of therapy. If treatment is to be undertaken with curative intent, a greater likelihood of side effects is accepted because of greater long-term benefit. In palliative treatment it is accepted that survival is likely to be relatively short, and the primary goal is to improve quality of life, which in veterinary medicine may result in prolonged survival because euthanasia is delayed. Therefore the drug doses and schedules used are less likely to result in side effects. Because quality of life for humans depends largely on preservation of body image and essential organ function, owners may interpret their pet's well being in similar terms; the clinician can help them to understand that these are not necessarily valid for animals. A continuing, open dialogue will allow an owner to make an informed decision and will ultimately create a “team” approach to treatment of the pet's cancer.

178.2 TUMOR BIOLOGY IN CHEMOTHERAPY

In general, chemotherapy drugs are most active against cells that are actively dividing and in a particular phase of the cell cycle. In the cell cycle, cells may be in mitosis (M phase), or undergoing RNA and protein synthesis (G_1 and G_2 phase) or DNA synthesis (S phase, which occurs between G_1 and G_2). Cells may also exit the active cell cycle and enter G_0, during which time they are mitotically quiescent and may not be affected by chemotherapy. The proportion of cells in G_1, G_2, S, and M phases (the active phases of the cell cycle) compared with G_0 is referred to as the *growth fraction*. Thus it is most advantageous to use chemotherapy when tumors have a relatively high growth fraction.

Tumors grow most rapidly when they are small. As they grow larger, the growth rate decreases due to a decrease in the proportion of cells in active phases of the cell cycle, increased loss of cells, and cell death due to poor circulation, poor nutrition, and hypoxia. This decrease in growth fraction as tumors age is referred to as *Gompertzian growth*. Larger tumors may also have a poor blood supply; thus chemotherapy drugs may not be delivered to cancer cells at cytotoxic levels. In addition, resistance to chemotherapy can occur through spontaneous mutations that occur with each cell division at a rate intrinsic to each tumor. Thus the likelihood that mutation resulting in drug resistance has occurred is related to the number of cell divisions that have taken place, and therefore resistance to chemotherapy is more likely in large tumors. Furthermore, the larger the absolute number of tumor cells present, the higher the likelihood that a resistant clone is present. Finally, chemotherapy cytotoxicity follows fractional-kill kinetics; for example, if a particular dose of drug kills 4 logs of cells, then it will reduce a tumor of 10^{13} cells to 10^{9} cells and a tumor of 10^{10} cells to 10^{6} cells. Either will appear clinically as a complete response; however, the latter scenario is obviously preferable. Therefore it is most advantageous to begin treatment with the smallest tumor, and in general, chemotherapy will be most active either after early detection or after a cytoreductive (“debulking”) procedure such as surgery or radiation therapy. Except in

vincristine treatment for canine transmissible venereal tumor and combination chemotherapy for lymphoma, chemotherapy is rarely effective for large bulky tumors.

178.3 CHEMOTHERAPY STRATEGIES

Before undertaking any treatment, it is important to determine a definitive diagnosis of tumor type, the clinical stage of disease, and the patient's overall health. The histologic diagnosis and stage are important both in establishing a prognosis and prescribing a treatment plan. The prognosis assists the client in choosing a goal of treatment. The general health screen is necessary to determine if other conditions are present that may affect the patient's life expectancy (i.e., other systemic disease), conditions that need to be resolved prior to starting chemotherapy (e.g., subclinical urinary tract infection), or conditions that need to be taken into account in planning chemotherapy (e.g., subclinical cardiac or renal disease).

178.3.1 Goal of Treatment

As discussed previously, it is important to determine the goal of treatment at the start of therapy, because the goal usually determines the course of treatment.

Cure is the eradication of all tumor cells and is an ideal outcome, although not always realistic in veterinary oncology. The restriction on chemotherapy doses to keep side effects within an acceptable range in veterinary oncology means that cures are only possible in a small number of patients. Often defined as 2 years of unmaintained remission (not receiving chemotherapy), cure is possible for up to 15% of dogs with lymphoma and 20% of dogs with osteosarcoma.

Palliation is designed to improve quality of life—and thus possibly to extend life—but without expectation of cure. Palliative treatment is often done when the prognosis is poor and significant toxicity cannot be justified in the face of a short expected survival. It is rarely effective to begin treatment with palliative intent and then later to switch to a more aggressive approach. However, it is common to begin treatment with curative intent and then later switch to a palliative course.

708

709

178.3.2 Treatment Response

To determine if a given treatment is effective, it is necessary to evaluate treatment response at each visit. This is important to avoid unneeded expense and toxicity from continuing to administer an ineffective drug and so that a more effective treatment can be instituted. Clinicians can determine the tumor volume by measuring each tumor in three dimensions when possible and multiplying them. If multiple masses are present, they are each measured and the total tumor volume for the patient is determined. The response to treatment is then determined as follows:

- Clinical remission/complete response (CR)—No evidence of any detectable tumor by routine physical exam and imaging techniques but not necessarily the same as cure
- Partial response (PR)—A decrease in tumor volume of greater than 50% and no new masses
- Stable disease (SD)—A decrease of less than 50% or increase of less than 10% in tumor volume
- Progressive disease (PD)—An increase in tumor volume of greater than 10% or the appearance of any new masses

178.3.3 Combination Chemotherapy

To understand combination chemotherapy, it is necessary to have a brief overview of the common classes of drugs in use in veterinary oncology.

Alkylating agents create cross-links in DNA, causing strand breaks. An interesting feature of this class of drugs is the apparent lack of cross-resistance between different alkylating agents or with other classes of drugs.

Antitumor antibiotics (anthracyclines) act by interfering with topoisomerases, DNA intercalation, and other mechanisms. These drugs usually exhibit cross-resistance with others in their class and with drugs in other classes, particularly mitotic inhibitors.

Mitotic inhibitors act to inhibit assembly (vinca alkaloids) or disassembly (paclitaxel) of the mitotic spindle.

Platinum compounds create cross-links in DNA. These drugs are similar to alkylating agents, and no cross-resistance with other classes of chemotherapeutic drugs is seen.

Antimetabolites are analogs of normal metabolites and are incorporated into DNA where they interfere with enzyme activity, transcription, or translation. These drugs often have significant toxicity with low efficacy at veterinary doses and so are not in frequent use in veterinary oncology.

Early therapeutic trials for the treatment of lymphoma using single-agent chemotherapy drugs, such as vincristine or cyclophosphamide, produced dramatic clinical responses in both dogs and cats. However, these responses were often of short duration, and further treatment using the same drug did not provide further response. In other words, these animals had resistant tumors. Tumor resistance to chemotherapy is common even before treatment is started, and tumor cells acquire resistance rapidly after drug exposure due to their high mutation rate.

Combination chemotherapy may overcome some of these problems by affecting different metabolic pathways in cells that are resistant to other drugs in the combination. The object is to kill cells that may be resistant to drug A by a different mechanism using drug B before the drug A–resistant clone has a chance to expand and develop cross-resistance. Although combination chemotherapy could potentially be more toxic to normal cells, patterns of toxicity vary between drugs, and judicious scheduling of chemotherapeutic agents so that their toxicities do not overlap appears to improve tumor kill without compounding toxicity. For example, drugs that do not produce significant bone marrow suppression (such as vincristine or L-asparaginase) may be scheduled to be given 1 week after a myelosuppressive agent (doxorubicin, cyclophosphamide) or even on the same day in combination. When chemotherapy combination regimens are designed, each drug included must be at least partially effective against the target tumor as a single agent. When drugs are given in combination on the same day it is sometimes necessary to reduce the dose of each individual drug for a higher total dose intensity. However, care must be taken not to reduce the dose of a highly effective drug to allow administration of a less effective one. The drugs are then scheduled, taking into account both the mechanism of action and the toxicity profile of each drug, to expose the tumor to the highest possible number of agents and maximize dose intensity while minimizing toxicity.

To reduce the risk of drug resistance occurring, it is important not to administer drugs at subtherapeutic doses; the highest dose intensity possible should be delivered. It is important not to modify the planned doses or schedule in anticipation of a toxicity that has not occurred. For example, a dog that became neutropenic after receiving doxorubicin is not at increased risk for myelosuppression from other chemotherapeutics such as

cyclophosphamide, so doses should not be reduced. It is also important not to change the protocol for short-term or nonlife-threatening toxicities such as emesis or diarrhea. On the other hand, if tumor growth occurs, it is not good practice to continue the same treatment protocol at the same doses. Instead, an alternative, noncross-resistant regimen should be used.

Although bacterial culture and sensitivity testing appears reliable, similar tests for chemotherapeutic sensitivity using tumor cells do not appear to have the same power of prediction. Such tests appear able to predict drug resistance and may have a role in identifying agents that could cause side effects without antitumor effects. However, because the ability of such tests to predict tumor sensitivity is low, combination chemotherapy is recommended over single agents suggested by assays.

178.3.4 Chemotherapy in Combination with Other Treatment Modalities

Chemotherapy can be used in combination with other modalities, including surgery, radiation therapy, or both.

Adjuvant chemotherapy is used after resection of a primary tumor, when the animal is at significant risk of recurrence or metastasis. The most obvious veterinary example is the effectiveness of adjuvant cisplatin, doxorubicin, or carboplatin in the treatment of canine osteosarcoma. The effectiveness of adjuvant chemotherapy lies in the fact that it is used at the earliest stages of growth. When a primary tumor is resected, micrometastatic foci of tumors cells have a high growth fraction and a low number of resistant cells. As the tumors grow, the growth fraction decreases, the cell cycle time increases, cellular heterogeneity increases (leading to a higher level of spontaneous resistance), and areas of poor vascular perfusion increase. The disadvantage of adjuvant chemotherapy is that some patients may be cured with surgery, and the animals are exposed to needless risks of toxicity. For tumors such as osteosarcoma and hemangiosarcoma in dogs and mammary tumors in cats, this percentage is small, but for animals with other tumors, the decision may be more difficult.

Neoadjuvant chemotherapy is used prior to localized treatment modalities such as surgery or radiation therapy with the objective of reducing the size of the primary tumor and reducing the scope and side effects of other definitive treatment.

Chemoradiotherapy refers to the use of chemotherapy drugs primarily as radiation sensitizers rather for their direct antitumor effect.

178.3.5 Modes of Administration

The majority of chemotherapy is delivered either intravenously or orally, and occasionally subcutaneously or intramuscularly. However, other modes of administration are sometimes used, particularly for cisplatin. *709* *710*
Cisplatin can be delivered to dog as an intracavitary infusion into the pleural or peritoneal cavities to successfully control malignant effusions or intravesicularly (into the urinary bladder) for bladder tumors. Cisplatin has also been injected intralesionally, in a collagen or oil-based vehicle, to control localized tumors. In this method, great care must be taken to avoid exposure of personnel because spillage occurs easily and drug may leak from the injection sites. Topical administration is available (5-fluorouracil—dogs only) but is rarely used because of drug toxicity and the risk of exposure to humans who apply the medication and play with the dog. Certain drugs can also be administered intra-arterially and intrathecally for specific treatment protocols; however, this is rarely done in veterinary medicine.

Encapsulation in liposomes can reduce or alter the toxicity of some chemotherapy drugs. Conjugation of the liposome with polyethylene glycol reduces clearance by the reticuloendothelial system, producing “stealth”

liposomes with greater circulating time. A liposome-encapsulated doxorubicin formulation has been reported to be less cardiotoxic in veterinary patients but resulted in a new cutaneous toxicity.

178.3.6 Chemoprotection

The administration of a second drug specifically to reduce the host organ toxicity of a chemotherapy drug is termed *chemoprotection*. Chemoprotectants in use in human and veterinary oncology include mesna, which reduces the risk of cystitis associated with ifosfamide and cyclophosphamide by binding toxic metabolites in the urine, and dexrazoxane, which protects against doxorubicin-associated chronic cardiotoxicity.

178.3.7 Metabolic Dosing

Because their desired effect is cellular cytotoxicity, most chemotherapy drugs have a very narrow therapeutic margin; that is, the host toxic dose is very close to the effective dose. Therefore it is important to be as accurate as possible when calculating doses. For some drugs, dosing is based on a “metabolic body size” to decrease the risk of toxicity to the patient. Although imperfect, current dose recommendations for these drugs are based on body surface area (BSA, m^2). This scheme implies that smaller animals have a higher metabolic rate and therefore should receive a higher dose on a body weight basis. For other drugs (e.g., doxorubicin) dose based on BSA is imperfect, and small dogs and cats should be dosed at lower rate than larger dogs. Until further guidelines are available, the veterinarian should check the dosing basis for any drug to be used, become familiar with the individual drugs that require lower dose for small pets, and use a BSA conversion table when metabolic dosing is indicated.

In human oncology, dosing is sometimes tailored to the individual patient either by monitoring drug levels or based on patient characteristics. For example, the appropriate dose of carboplatin can be determined from a formula based on the patient's glomerular filtration rate (GFR) and the desired area under the curve (AUC). This type of calculation is not usually done in veterinary oncology; however, similar principles are recognized: in patients with reduced GFR reflected as elevated serum creatinine level, carboplatin dosing should be adjusted based on the serum creatinine level (see Practical Chemotherapy).

178.3.8 Dose Intensity

The concept of dose intensity is an important principle of chemotherapy. It is defined as mg/m^2 of drug per week of therapy and should be the highest tolerated by the animal with minimal toxicity. For example, in dosing of myelosuppressive drugs, because there will be variation in individual metabolism of drugs and in the sensitivity of normal tissues, the aim should be to deliver doses that produce a neutrophil nadir of between 1000 and 1500 cells per μl. Ample evidence in both human and veterinary oncology suggests that optimal dose intensity improves the outcome for chemotherapy.

Chemotherapy dose intensification with bone marrow support has been used with success in veterinary oncology. The use of autologous (patient's own) bone marrow transplant to allow higher doses of a myelosuppressive drug has been used in myeloablative bone marrow transplantation in human patients and dogs, but the toxicity of such dose intensification is high. Intensifying chemotherapy doses with autologous bone marrow support, but only into the submyeloablative range, appears to improve remission times without increasing toxicity for selected dogs with lymphoma.

178.3.9 Toxicity After Chemotherapy

Because most chemotherapy drugs are effective in the active phases of the cell cycle, toxicity from chemotherapy is most common in tissues that are renewing and is usually related to the dose of the drug. This has implications for both the patient (toxicity and efficacy) and for owner and veterinary staff safety in handling the drugs during administration and patient care. (See Practical Chemotherapy for more on chemotherapy safety.) Although most tumor cells are in active phases of the cell cycle, most normal tissues have a relatively low growth fraction. Normal tissues can be classified as static (nerve, striated muscle) in which the capacity for mitosis is limited; expanding (organs, glands) in which mitosis can be induced; and renewing (hematopoietic cells, mucosa, epidermis, gametes, fetal tissues) in which the growth fraction approaches that of tumor tissue. The major toxicities of chemotherapy affect the latter group.

Myelosuppression is a general term applied to the toxic effects of chemotherapy on the bone marrow (Table 178-1). In general the prognosis for uncomplicated myelosuppression is good, and most veterinary patients recover within a few days. Most dogs and cats that have myelosuppression have no clinical signs at all. The most chemosensitive cells in the bone marrow are the proliferating hematopoietic progenitors and precursors, which are starting to commit to a particular lineage but are still immature. The more differentiated cells form a nonproliferating pool of maturing hematopoietic cells that will be unaffected by chemotherapy and will provide mature cells for 5 to 10 days. This means that the nadir (or low point) of peripheral cell counts occurs at this time. The time at which the nadir occurs also depends on the life span of the hematopoietic cell. Neutrophils live only hours in both dogs and cats, and their nadir occurs first at 5 to 10 days postchemotherapy; platelets live for approximately 10 days, and their nadir occurs 1 to 2 weeks after chemotherapy. Erythrocytes live for 120 days in the dog and 70 days in the cat; although anemia may occur over a prolonged course of chemotherapy, it is rarely clinically significant. Like the maturing cells, hematopoietic stem cells are largely nonproliferating and so are relatively resistant to chemotherapy toxicity. However, they are stimulated to divide by the loss of proliferating precursor cells and rapidly replace the lost cells so that nadirs after chemotherapy rarely last more than several days. This also has implications for the interval between administrations of myelosuppressive drugs. If these drugs are given when the stem cell pool is dividing (i.e., soon after the previous administration), then severe prolonged myelosuppression due to stem cell destruction may occur. The usual timing for myelosuppressive drug administration is every 2 to 3 weeks. Some drugs (such as lomustine and carboplatin) may have delayed or prolonged nadirs, and dosing intervals are longer for these drugs.

When administering chemotherapy, a complete blood count (CBC), including a platelet count, should be collected at the expected neutrophil nadir, usually 1 week after administration. The absolute neutrophil count (not the total leukocyte count) should be evaluated. Although many animals have a low neutrophil count without clinical signs, a count of less than 1000 cells per µl is sufficient reason to reduce all subsequent doses of that myelosuppressive drug.

Table • 178-1 Myelosuppressive Potential of Some Commonly Used Chemotherapeutic Agents

HIGHLY MYELOSUPPRESSIVE	MODERATELY MYELOSUPPRESSIVE	MILDLY MYELOSUPPRESSIVE
Doxorubicin	Melphalan	L-asparaginase*
Vinblastine	Vincristine (0.75 mg/m2)*	Vincristine (0.5 mg/m2)*
Cyclophosphamide	Methotrexate	Corticosteroids
Carboplatin	Cisplatin	Bleomycin
Mitoxantrone	Chlorambucil	
Lomustine (CCNU)	Hydroxyurea	
	5-Fluorouracil	

* However, the combination of vincristine and L-asparaginase can be highly myelosupportive.

Thrombocytopenia rarely causes clinical signs; however, at counts less than 50,000, the risk of bleeding increases and the veterinarian should be alert to petechiation, ecchymoses, or mucosal bleeding.

The gastrointestinal (GI) mucosa is another site of renewing tissue, and toxicity may occur anywhere in the GI system. Clinical signs include nausea, vomiting, inappetence, anorexia, or diarrhea. The management of this toxicity will depend on the severity of signs. Again, most GI toxicity is mild, self-limiting, and carries a good prognosis. For inappetence, tempting with palatable foods or using appetite stimulants such as cyproheptadine may be helpful. For occasional or mild vomiting, withholding food for 24 hours, then introducing multiple small feedings of a bland diet is usually sufficient. Metoclopramide may reduce the severity of vomiting; for diarrhea in dogs, subsalicylate may be therapeutic. For severe GI signs, intravenous fluid support and antiemetic treatment should be considered. Antiemetics include metoclopramide infused at a constant rate, chlorpromazine, or ondansetron (a serotonin antagonist that is an excellent antiemetic). Cisplatin is a powerful emetogen, and the prophylactic administration of butorphanol immediately after cisplatin administration reduces both the incidence and severity of vomiting. Ondansetron may also be used in the same setting. If vomiting occurs after cisplatin treatment (and particularly if it is prolonged or associated with anorexia), intravenous fluids should be administered, because dehydration may exacerbate the nephrotoxic effects of cisplatin. Severe hemorrhagic colitis after doxorubicin administration increases the risk of subsequent sepsis due to breakdown of the protective mucosal barrier to gram-negative intestinal bacteria at a time when the animal is myelosuppressed. Antibiotics should be administered to these animals in addition to supportive and symptomatic care.

In veterinary oncology, cardiotoxicity is only clinically a problem with doxorubicin chemotherapy. Although both cats and dogs show histologic cardiac changes, cats have not been reported to have clinical cardiotoxicity. Acute cardiotoxicity is related to peak plasma level and occurs during administration that is too rapid. Although the arrhythmias are self-limiting, they can cause collapse. The infusion should be stopped and then restarted at a slower rate. Chronic cardiotoxicity is related to the total cumulative dose of doxorubicin rather than the amount of each individual dose, and it carries a poor to grave prognosis. The end result resembles dilated cardiomyopathy and may progress to congestive heart failure (CHF). Although cardiotoxicity in dogs can occur at any cumulative dose, it is most frequent above 180 mg/m^2, and doxorubicin should not be given above this level without echocardiographic monitoring. Electrocardiographic changes are inconsistent and a poor indicator of early cardiac damage. Although echocardiographic changes usually occur before clinical signs, the damage will progress even after doxorubicin has been discontinued. Breeds susceptible to dilated cardiomyopathy, particularly Dobermans, appear to be more sensitive to this toxicity; pretreatment cardiac evaluation and close monitoring is mandatory in these dogs. The risk of cardiotoxicity is reduced by delivering the drug as a

continuous infusion over several hours, by using liposome-encapsulated doxorubicin, or by pretreatment with the cardioprotectant drug, dexrazoxane. The latter two options are yet to be fully evaluated in clinical veterinary practice.

Nephrotoxicity is the primary dose-limiting toxicity of cisplatin and depends on both the individual and cumulative dose. This toxicity also carries a poor prognosis. Cisplatin should not be administered to dogs with pre-existing renal disease and should be used with caution in dogs with urinary tract tumors. It is important to check the serum creatinine level before each cisplatin treatment. Cisplatin should not be administered if the serum creatinine is above normal range. In addition, cisplatin should always be delivered with appropriate saline diuresis. Doxorubicin has been anecdotally associated with nephrotoxicity in cats.

Urothelial toxicity (sterile hemorrhagic cystitis) is associated with cyclophosphamide and ifosfamide administration. Although this toxicity is uncommon after cyclophosphamide administration, it will occur after ifosfamide treatment unless the urothelial protectant, mesna, is given concurrently. When it occurs, it is usually self-limiting and carries a fair to good prognosis. Clinical signs of stranguria, dysuria, and hematuria can be severe and prolonged over many weeks. This toxicity should be distinguished from infectious cystitis by bacterial culture; however, even if bacteria are isolated and signs resolve with antibiotic administration, the drug should not be administered again because infectious cystitis could have been secondary to chemical cystitis. Chlorambucil is usually substituted for cyclophosphamide if urothelial toxicity occurs in lymphoma patients. If urothelial toxicity occurs, steroidal or nonsteroidal anti-inflammatory drugs (NSAIDs) may reduce the severity of signs. In persistent cases, intravesicular instillation of 25% dimethyl sulfoxide (DMSO) for 20 minutes may help reduce signs and may be repeated weekly.

Extravasation is rarely a problem if chemotherapy is administered carefully through a “first-stick” venous catheter. The catheter should be tested with a saline flush both before the drug is administered and after infusion is complete.

711

712

Although a butterfly catheter is acceptable for volumes less than 1 mL, larger volumes should be administered through a secure over-the-needle catheter. If any drug is extravasated, the clinician should aspirate as much drug as possible before removing the catheter. If vincristine is extravasated, the area should be flooded with 10 mL of 0.9% NaCl and warm compresses applied. The resulting reaction is rarely severe and will be reduced further by preventing self-trauma. If doxorubicin is extravasated, ice compresses should be applied for 6 to 12 hours. Dilution of drug will only increase the area affected. Doxorubicin extravasation results in a slough that can be severe, and the full extent of the reaction may not be apparent for 3 to 4 weeks. Surgical resection or débridement may be necessary.

Hypersensitivity reactions may occur during doxorubicin administration due to histamine release from mast cells. This effect only occurs with rapid administration and is not a problem if the drug is given as a slow infusion or an intravenous injection at a rate of 1 mL per minute. A similar but more severe reaction occurs after intravenous administration of etoposide and paclitaxel due to “carrier” solutions in these formulations. Both carriers cause massive histamine release, the effects of which are only partly prevented by pretreatment with antihistamines and corticosteroids. True anaphylaxis may occur after L-asparaginase administration, particularly by the intravenous or the intraperitoneal route. This toxicity occurs very rarely if L-asparaginase is administered intramuscularly or subcutaneously. If anaphylaxis occurs, treatment with corticosteroids and antihistamines plus any necessary supportive measures should be instituted. The patient should not receive any further L-asparaginase. Attachment of polyethylene glycol conjugates to the L-asparaginase abrogates the immune response, and extends its half-life while preserving efficacy.

Hair loss is rarely a problem in pets that have fur. However, in dog breeds with hair (e.g., poodles, terriers, old English sheepdogs), alopecia can be significant although regrowth usually occurs in 4 to 8 weeks. In addition, dog breeds with “feathers” will lose these (e.g., golden retrievers). Cats will lose whiskers and sometimes body fur, and they may experience hair coat color changes. These problems are cosmetic and rarely of consequence to an adequately prepared owner.

Specific cat toxicities may occur with chemotherapy. Cisplatin causes a fatal, acute pulmonary edema in cats and should not be administered systemically. Intralesional administration of a colloidal suspension of cisplatin may be safe in cats, but care should be taken if this route is to be used. Topical and systemic administration of 5-fluorouracil causes acute fatal neurotoxicity in cats, and products containing this drug should not be used.

The major dose-limiting toxicity in veterinary cancer chemotherapy is myelosuppression. Recombinant hematopoietic growth factors and autologous bone marrow transplantation are widely available in human oncology practice and are in the initial stages of evaluation in veterinary oncology. Such techniques may allow the use of higher dose intensity without increasing the risk of myelosuppression. Similarly, advances that are being made in the treatment of pain and nausea and in the prevention of toxicities such as cystitis (mesna with ifosfamide or cyclophosphamide) will reduce the incidence of other toxicities. These will improve the ability of the veterinary oncologist to deliver adequate chemotherapy doses and result in better quality of life for pets with cancer.

178.3.10 Chemotherapy Drug Resistance

Resistance to chemotherapy may be either inherent or acquired. Drugs may be physically unable to reach tumors that are in sanctuary sites such as the central nervous system (CNS) or that are poorly perfused. Tumor cells may inherently lack receptors for a drug or not be susceptible to the mechanism in some other way (e.g., cells that have asparagine synthetase will be resistant to L-asparaginase).

Tumor cells may develop drug resistance spontaneously through mutation. The mutation rate is higher in tumors than in normal tissue because of the genetic instability characteristic of malignancy. With each cell division comes the risk of a resistance mutation; therefore the larger a tumor is (i.e., the more cell divisions it has undergone), the higher the likelihood that this has occurred. Tumor cells can also develop drug resistance specifically. Exposure to sublethal drug concentrations can result in gene amplification of detoxifying proteins.

Although combination chemotherapy may circumvent individual drug resistance, it does not avoid the problem of cross-resistance to multiple unrelated chemotherapy drugs. The transmembrane pump protein (P-glycoprotein) is present at increased levels in some tumor cells, and both the level and prevalence increases with exposure to chemotherapy. This phenomenon of multiple drug resistance (mdr) occurs between anthracyclines, mitotic inhibitors, and others. However, alkylating agents are not substrates for the mdr pump, and so they become the mainstay of treatment in patients that appear to have this type of drug resistance.

This chapter is best read in conjunction with Chapter 178, Principles of Chemotherapy. The two chapters include many of the same topics, but they are complementary in their treatment of those topics.

179.1 CLIENT PREPAREDNESS

The greatest challenge the veterinarian faces in using chemotherapy is addressing owners' preconceptions, biases, and negative experiences with chemotherapy. The side effects of treatment in human patients, which the owner may have experienced or may have heard about from television, the Internet, or family and friends, usually are inconsistent with the quality of life clients want for their pet. It is important for the veterinarian to acknowledge these feelings and to inform the owner that the goal of chemotherapy in cats and dogs is different; that is, that the pet should be given the maximum dose that improves quality of life without causing undue toxicity, as defined by the veterinarian and the owner. For some owners, this definition may mean preventing *any* loss of quality of life; for other clients, it may have a much different meaning. In any situation, the veterinarian should establish the goals of therapy before starting treatment. If owners understand that quality of life takes precedence in their pet's treatment they are more likely to trust the veterinarian and to treat their pet. The reality of supportive care for cancer chemotherapy patients in veterinary medicine is that component transfusions, sterile wards, and allogeneic transplant support are unavailable. For these reasons, lower drug dosages must be used, and dosages must be reduced even further if toxicity is observed. This should be emphasized to owners.

Provision of accurate information in understandable terms about the type of cancer, the prognosis, and the predictable side effects of treatment is an important responsibility of any veterinarian. Being honest while maintaining a feeling of hope and caring is one of the most important aspects of establishing trust with the owners of a pet with cancer. Encouraging owners to ask questions and to communicate their concerns is equally important.

Supplementation of verbal instructions with written information about the specific disease, the treatment protocol, and the drugs to be used greatly assists owners in making their decision. Many such information sheets can be obtained from veterinary oncologists and the Internet.

Furthermore, it is important to discuss with owners not only the potential toxicities of treatment, but also the owners' goals for chemotherapy, in particular what they would consider a successful outcome.

179.1.1 Palliative Intent Treatment

For many older veterinary patients, the diagnosis of cancer is made at a time when other diseases may limit survival to a greater extent than does the cancer. For these animals, palliative care may be most appropriate, and the choice of chemotherapy must be weighed against the risk of toxicity. An example would be a Doberman pinscher with cardiomyopathy and osteosarcoma. Such a dog may benefit from pain relief for the bone cancer. Cardiac disease makes doxorubicin a poor choice for chemotherapy, and the diuresis required for cisplatin administration may result in cardiac decompensation. An alternative, therefore, would be carboplatin. However, if a poor prognosis due to cardiac disease makes it unlikely that the benefits of extended survival through chemotherapy will be realized, chemotherapy may not be a good choice for this pet, and treatment should focus on pain relief.

179.1.2 Curative Intent Treatment

For younger dogs and cats that are in good health and have no concurrent illnesses and for which chemotherapy holds the possibility of prolonged control of the cancer with little risk of toxicity, chemotherapy with curative intent may be undertaken. An example would be an asymptomatic, middle-aged dog with stage 3, B-cell lymphoma, for which the prognosis is guardedly optimistic. The owners of such a dog may even elect to try more aggressive combination chemotherapy to improve the chance of long remission.

179.2 SUITABILITY OF THE PATIENT

When evaluating an animal for treatment of cancer, it is important not only to obtain a definitive diagnosis, but also to assess the pet's general health through clinical examination and ancillary diagnostics. Prognostic information gained by determining the extent of organ involvement by the tumor and by identifying unrelated or secondary conditions that must be treated or controlled before the appropriate therapy can be instituted is mandatory in order to make recommendations regarding the suitability of a patient for chemotherapy. This information is also vital for individualizing the type and intensity of a treatment regimen.

179.2.1 Staging and Health

Staging is a clinical process that enables the veterinarian to quantitate the extent of cancer involvement in the dog or cat. Staging is sometimes confused with *grading,* which characterizes the histopathologic features of a tumor. Staging often carries prognostic significance that may help both the veterinarian and the client make informed, rational decisions about the type of therapy best suited for a pet. Most staging systems are based an assessment of three major components of the malignant process: the size of the primary tumor (T), lymph node metastasis (N), and distant metastasis (M). Ancillary diagnostics, often incorporating sophisticated imaging techniques, are important for obtaining this information. The majority of pets for which chemotherapy may have therapeutic benefit have systemic or metastatic disease that either is physically evident or is presumed through historical knowledge of tumor behavior (e.g., osteosarcoma and hemangiosarcoma in dogs).

The likelihood of a successful outcome for a dog or cat treated with chemotherapy is as dependent on drug metabolism and elimination (and drug absorption for orally administered chemotherapy) as it is on the sensitivity of the tumor.

713

714

Consequently, information gained during staging may identify problems that can affect the type and dosage of chemotherapy, in order to optimize efficacy while limiting toxicity. For example, hepatic dysfunction may lead to delayed elimination of some drugs (e.g., vinca alkaloids, doxorubicin) and therefore to greater toxicity, such as myelosuppression. In contrast, because cyclophosphamide is activated in the liver, hepatic dysfunction may result in poor efficacy.

Similarly, renal dysfunction may worsen toxicity for some drugs that are themselves nephrotoxic. For example, cisplatin and streptozocin should not be used in animals with renal azotemia. Reduced renal excretion of carboplatin exacerbates myelosuppression.

Particularly in breeds with a predisposition to the development of cardiomyopathy, treatment with doxorubicin should be accompanied by cardiac evaluation. Pretreatment echocardiography should be performed, and dogs with reduced contractility should not be given doxorubicin. Although valvular dysfunction should not be a reason to withhold doxorubicin, mild changes in cardiac muscle function may exacerbate the valvular disease.

In these dogs, echocardiography should be performed periodically, ideally prior to each doxorubicin treatment. Treatment with doxorubicin should be discontinued if contractility is below normal and while the dog is still asymptomatic. Cardiac dysfunction caused by doxorubicin is irreversible and usually progressive. For this reason, monitoring for signs of early cardiac failure before discontinuing doxorubicin is unacceptable practice.

179.3 SUITABILITY OF THE TUMOR

The most rapidly changing aspect of veterinary oncology involves published data on tumor sensitivity to chemotherapy. Although good published data are available on dogs with osteosarcoma and lymphoma, information on the most effective chemotherapy for adjunctive treatment of other, even common, malignancies often is unavailable or is based on small case series. As larger, multi-institutional and organizational studies are completed and the results published, this will change. For example, the recent finding that high-grade soft tissue sarcomas in dogs are more likely to metastasize implies that it may be possible to assess adjunctive chemotherapy for efficacy in this select group of dogs. In contrast, appendicular osteosarcoma in cats rarely metastasizes (approximately 25%), and it would be difficult to demonstrate adjuvant efficacy for any chemotherapeutic agent, given the rarity of the tumor.

179.4 CHOOSING A DRUG

Clinical veterinary chemotherapy research is advancing at a great rate. However, even when studies are completed, it may be a year or more until the results are published, and they often appear in less accessible journals. The best resources for veterinarians are veterinary oncologists, the Veterinary Cancer Society (www.vetcancersociety.org), other Internet-based resources and Internet literature data bases, such as Medline.

In addition to efficacy, and possibly more important, the final choice of a drug (or protocol) depends on toxicities, an owner's tolerance for side effects, the treatment goals, the cost, and the veterinarian's level of comfort in delivering chemotherapy and supportive care.

179.5 CHEMOTHERAPEUTIC DRUGS

No chemotherapeutic drugs are labeled for veterinary use only. All veterinary cancer chemotherapy is performed off label. However, most of the available drugs have an established track record, particularly those that have been used to treat lymphoma and osteosarcoma. The body of literature available means that veterinarians should feel secure in using dosages and schedules provided in published protocols. Treatment using most veterinary drugs is expected to result in less than 5% risk of life-threatening toxicity (hospitalization, severe neutropenia) when established dosages are used. The risk of death from chemotherapy should be considerably lower than that.

179.5.1 Drug Cost

The cost of many of these drugs may be high. However, generic versions of several chemotherapeutic agents (e.g., vincristine, doxorubicin, cisplatin) are available, making them more affordable. Some pharmacies supply small amounts of injectable drugs to veterinarians, and compounding pharmacies will reformulate smaller dosages of oral medications (e.g., lomustine [CCNU] or procarbazine for cats and small dogs). The cost of therapy often is not as much a deterrent to owners interested in chemotherapy for their pet as is quality of life. Veterinarians should inform owners of the best available options and allow them to make the decision on cost.

179.6 WHEN TO GIVE CHEMOTHERAPY

Veterinary chemotherapy protocols are often simple, consisting of one or two chemotherapy agents given at an interval that minimizes the risk of toxicity but maintains the highest possible dose intensity (e.g., cisplatin as an adjuvant to surgery for dogs with osteosarcoma). In contrast, lymphoma protocols are often complex, with many agents scheduled in combination (see Tufts VELCAP-SC, Figure 179-1). Descriptions of different "phases" of a protocol apply best in these lymphoma treatment schedules.

179.6.1 Timing

179.6.1.1 Primary Treatment

In veterinary oncology, primary chemotherapy usually is reserved for hematopoietic tumors (lymphoma, leukemias, multiple myeloma). The phases of a primary treatment protocol for lymphoma are presented in Box 179-1. Chemotherapy for dogs with metastatic solid tumors (carcinomas and sarcomas) is rarely successful and is better considered to be palliative.

179.6.1.2 Adjuvant Treatment

After surgery, adjuvant chemotherapy may be given to slow the progress of metastatic disease or possibly to provide a cure. The optimum time to administer primary chemotherapy is when the dog or cat has microscopic disease, rather than when gross metastases have developed. An example of successful adjuvant veterinary chemotherapy is the use of platinum compounds and doxorubicin after surgery for canine osteosarcoma.

179.7 ADMINISTRATION OF CHEMOTHERAPY

The proper administration of chemotherapy has been covered in great detail by many authors. In brief, the regulations set by the U.S. Occupational Safety and Health Administration (OSHA) should be followed, and owners, as well as all personnel coming in contact with chemotherapeutic agents, should be protected to the best of the veterinarian's abilities. A chemotherapy logbook, which includes identification of animals treated and the personnel involved in the treatments, should be maintained to track exposures.

179.7.1 Box • 179-1 Phases of a primary treatment protocol for lymphoma

179.7.1.1 Induction

The induction phase encompasses the often intensely scheduled initial treatments. During this phase, a dog or cat has a relatively higher risk of toxicity but usually also the greatest chance of response (e.g., during the first 12 weeks of VELCAP; see Figure 179-1).

179.7.1.2 Consolidation

Consolidation is sometimes used at the end of induction; unrelated, effective drugs are administered to further reduce the proportion of surviving cancer cells (e.g., the combination of mechlorethamine, vincristine (Oncovin), procarbazine, and prednisone [MOPP] and CCNU in VELCAP; see Figure 179-1).

179.7.1.3 Maintenance

Maintenance is a less intense phase (usually involving decreased frequency of administration) during which the drugs previously used for induction are administered. Maintenance therapy probably has little influence on whether an animal is cured, but it may prolong survival by increasing the time to relapse.

179.7.1.4 Rescue

Rescue is therapy given when the drugs used during the other three phases no longer result in remission. Unrelated drugs (often alkylating agents because they are less likely to show cross-resistance) are used for rescue therapy.

179.7.2 Handling

Veterinarians can greatly reduce the risk of exposure by familiarizing themselves with the hazardous properties included in the Material Data Safety Sheet (MSDS) for each drug and by using appropriate protective equipment. The information contained in each MSDS covers specific health hazards, including carcinogenicity; primary routes of exposure; protective equipment; treatment of personnel acutely exposed; chemical activators; solubility; stability; volatility; and specific procedures to be undertaken in case of a spill. The MSDS should be requested with the initial shipment of any chemotherapeutic agent and should be kept on file in an easily accessible location.

Most chemotherapeutic agents are both toxic and mutagenic. Alkylating agents have been associated with the highest risks to handlers. Organ damage and increased risk of fetal loss have been reported in individuals handling and administering chemotherapy with inadequate attention to personal safety. Precautions should be taken in handling chemotherapeutic drugs during any phase of preparation, administration, and disposal of drugs or waste. Ideally, a vertical laminar flow biologic safety cabinet would be used to prepare all chemotherapeutic drugs. If this is not available, protective eyewear, a respirator mask, and a disposable gown with closed-cuff sleeves and latex (not vinyl) gloves should be worn. All these items usually are available through distributors of chemotherapeutic agents. Hydrophobic filters that insert into chemotherapeutic drug vials can prevent aerosolization of drugs during preparation for dosing. If a filter is not used, gauze moistened with alcohol should be wrapped around the vial top and needle to protect personnel from aerosolized drug. Latex gloves should be worn when the drugs are administered, whether parenterally or orally. With parenteral administration, Luer-Lok syringes reduce the risk of drug leakage or spills. Pills should not be broken.

If owners are administering drugs orally at home, gloves and a waste bag should be provided. For drugs excreted in the urine (particularly cisplatin), the pet should be encouraged to urinate on soil where urine drains quickly, and any urine in other areas should be handled and disposed of as chemotherapy. These precautions should be followed for approximately 48 hours after administration.

179.7.3 Route of Administration

For most intravenous chemotherapy administrations, injection through a peripherally located over-the-needle catheter is safest, reducing the risk of extravasation even when a small volume is to be administered. For longer infusions (more than 30 minutes), a through-the-needle catheter is less likely to become dislodged.

When long infusions are required, either for prolonged drug delivery or for the saline diuresis that accompanies nephrotoxic drugs such as cisplatin or streptozocin, an infusion pump is recommended. Free-flowing fluid administration, even when monitored continuously, may not ensure continued diuresis or could result in uneven delivery of the drug dose. Both of these factors could affect the risk of toxicity. A calibrated infusion pump allows predictable administration of the chemotherapeutic dose.

Some cats and many dogs are small, and their vascular integrity may be compromised by multiple administrations of anesthesia (e.g., surgery, radiation therapy) prior to receiving chemotherapy. Because the risk of extravasation reactions is greater in these animals, an indwelling, subcutaneously located, implantable vascular access port may ensure timely drug delivery and reduce stress during restraint for catheter placement and administration of chemotherapy. Such a port may be maintained for the duration of therapy and then removed. The implantable vascular access port must be placed surgically, in a similar manner to a tunneled catheter, with a subcutaneous pocket for positioning of the port. Ports for veterinary use are available from Norfolk Vet Products, Skokie, Illinois.

Most oral medications are administered as tablets or capsules, although a cyclophosphamide elixir can be compounded using the injectable form of the drug. Tablet formulations should not be split, because distribution of the drug may not be uniform throughout the tablet; this is particularly true of cyclophosphamide. For small animals, reformulation of oral medications by a compounding pharmacy is more accurate and safer (e.g., CCNU or procarbazine for cats).

Intracavitary chemotherapy (intrathoracic, intra-abdominal, intrapericardial, or intravesicular [urinary bladder]) has been reported. The drugs used for this purpose logically should have little vesicant activity. The drugs most commonly used are the platinums (cisplatin may have greater tissue penetration than carboplatin) and mitoxantrone.

Intralesional chemotherapy usually involves a suspension of a chemotherapeutic agent in a vehicle (the use of cisplatin or 5-fluorouracil in sterile sesame oil or bovine collagen matrix has been reported). The mixture should be injected into a tumor, creating high drug exposure to tumor cells. This involves minimal systemic drug levels, avoiding the risk of systemic toxicity. Intralesional chemotherapy is used to treat only small, easily accessible tumors.

179.7.4 Dosing

The initial treatment with an individual drug should be given at a dosage known to result in minimal toxicity in the majority of animals. Because the risk of toxicity is highest when an animal receives a drug for the first time, the temptation may exist to begin with a low dose and increase the dosage incrementally after each administration that is toxicosis free. The logic of that approach is flawed, however, because the reduction in dose intensity can only reduce the chance for successful remission and accelerate the development of drug resistance. Effective treatment is more likely to result from the highest tolerated dosage, and prophylactic supportive strategies (see below) are preferable to an arbitrary reduction in the initial dosage.

715 716

The selection of drug dosage can also be influenced by organ function. Although no guidelines have been established, it may be safest to reduce the dosage of hepatically metabolized drugs by 50% if the serum bilirubin is greater than 1.5 mg/dL and by 75% if the serum bilirubin is greater than 3 mg/dL. Dosages can then be slowly increased after each cycle that occurs without toxicity.

Because carboplatin is renally excreted, carboplatin dosage ideally is based on the glomerular filtration rate (GFR). If the GFR cannot be estimated, an arbitrary dose reduction of 50% to 75% should be made for animals with renal azotemia; dosages then can be increased after each cycle that occurs without toxicity.

The frequency of drug administration is determined by the length of time required from administration of the drug to the recovery of normal tissues (bone marrow, gastrointestinal tract). For example, doxorubicin can be given every 2 weeks to most animals because neutropenia has usually completely resolved by this time. However, some individual patients may not be able to receive the drug any more often than every 3 weeks because of a neutrophil count that is still too low (see the section on monitoring, below). The drug that is the most common example of individual variability for dosing interval in veterinary medicine is carboplatin. In some animals (particularly cats), it may take 5 weeks or longer for hematologic parameters to recover to a level at which a subsequent dose can be delivered safely.

179.7.5 Drug Resistance

Chemotherapeutic drugs act through a multitude of mechanisms. Resistance to individual drugs may occur at the cellular level (e.g., altered target) or as a result of host factors (e.g., antibody formation to L-asparaginase). When combination chemotherapy is used, cross-resistance between different classes of agents is a serious threat to successful treatment. In particular, multiple drug resistance (MDR) due to a transmembrane efflux pump protein (gp170) can reduce intracellular levels of vinca alkaloids, anthracyclines, and other “naturally” derived chemotherapeutics to nontoxic levels. Because these drugs are often used in the treatment of lymphoma, it is wise *not* to overly rely on them in the rescue stage, but rather to use them in combination for first-line therapy. Interestingly, drugs classified as alkylating agents are not susceptible to the MDR mechanisms. There is very little cross-resistance, even between different alkylating agents. This may explain the successful strategy of using alkylating agents as rescue therapy for animals with lymphoma. It is also possible that the use of alkylating agents in combination with MDR-type drugs during the early phases of treatment (induction) may slow the onset of resistance. Trials of agents that competitively block MDR have not yet led to practical veterinary treatment strategies.

179.7.6 Drug Combinations

Combination chemotherapy has two major aims. The first is to slow the onset of drug resistance in tumor cells. As mentioned above, the use of agents with differing targets and mechanisms of action is most likely to provide long-term tumor control. In particular, the use of alkylating agents may slow the development of MDR (e.g., adding cyclophosphamide or the combination of mechlorethamine, vincristine (Oncovin), procarbazine, and prednisone [MOPP] to a chemotherapy protocol for lymphoma rather than using doxorubicin alone). The second aim of combination chemotherapy is to maximize tumor cell kill while minimizing toxicity. The combination of drugs that are myelosuppressive with drugs that are minimally myelosuppressive may fulfill this aim (e.g., cyclophosphamide and vincristine; doxorubicin and cisplatin). It is important that combinations comprise *effective* drugs; there is little use to using a nontoxic combination if one of the drugs has not been shown to be efficacious against the particular tumor type. Combinations, therefore, use drugs that have shown activity as single agents.

Some combinations may result in altered toxicity due to changes in the way a drug is metabolized or excreted. For example, L-asparaginase is thought to slow hepatic metabolism of drugs such as vincristine and doxorubicin, thereby increasing the risk of myelosuppression.

It is recommended that practitioners use only combinations for which published efficacy and toxicity data are available.

179.8 MONITORING OF ANIMALS WITH CANCER

179.8.1 History

Before chemotherapy is administered, drug dosages and toxicities, as well as the administration schedule, must be reviewed with the owner. After the chemotherapeutic treatment, the pet should be monitored at home for gastrointestinal or other toxicoses. In general, the use of antiemetics and appetite stimulants can prevent mild toxicities; diarrhea may be treated with dietary management or with sulfasalazine or metronidazole, as long as specific causes have been eliminated. Gastrointestinal toxicity usually occurs in the 4 to 5 days after treatment.

Chemotherapeutic doses should be reduced if the pet requires hospitalization for gastrointestinal signs or if such signs are unacceptable to the owner. A dose reduction of 25% for all subsequent administrations of that drug is a good rule of thumb, because with this reduction, it is unlikely that subsequent chemotherapy administration will be associated with toxicity. Supportive care, as both treatment and further prophylaxis, is mandatory.

179.8.2 Complete Blood Count

Neutropenia is a toxicity of many chemotherapy agents, and the nadir (lowest point) generally occurs 5 to 10 days after administration. A complete blood count (CBC) should be obtained 7 days after most treatments. Monocytosis on a CBC often predicts imminent neutrophil recovery, because monocytes have one fewer maturation step than granulocytes and therefore are released from the bone marrow earlier.

Neutrophil recovery is usually rapid; however, a nadir of less than 1000/μL should prompt a 25% dosage reduction for all subsequent administrations of that drug. It is not necessary to reduce the dosage of other myelosuppressive drugs, because they may not cause the same degree of suppression. Each drug should be assessed individually. If a dosage reduction is made, the nadir should again be assessed.

Neutropenia at the time of the next chemotherapy treatment is a reason to delay administration of a myelosuppressive drug (but not of a nonmyelosuppressive drug, such as L-asparaginase or prednisone). In general, a neutrophil count of less than 3000/μL requires a delay in chemotherapy, usually of 1 week, before the CBC is rechecked. If the pet takes a long time to recover (as occurs for many cats and some dogs after receiving carboplatin), it may be necessary to reduce the dosage so that the optimal intertreatment interval and dose intensity can be maintained.

716

717

Thrombocytopenia may be dose limiting for select chemotherapy agents (carboplatin, cumulative for CCNU), but is rarely clinically significant for other drugs. Platelet nadirs occur later than neutrophil nadirs, but are rarely as severe and recovery is slower but complete. Thrombocytopenia in a pet due to receive CCNU should prompt a dose reduction or discontinuation.

179.8.3 Serum Chemistry Profile

Renal function should be assessed by serum creatinine and urine specific gravity determinations prior to administration of nephrotoxic drugs (cisplatin in dogs; doxorubicin in cats) or renally excreted drugs (carboplatin). The dosages of these drugs should be adjusted as described above under Dosing.

Liver enzyme serum activity (alanine aminotransferase [ALT]) should be assessed prior to administration of lomustine. Irreversible hepatic toxicity can result if lomustine therapy is continued despite increases in serum ALT activity.

Increases in serum bilirubin should prompt dose reductions in hepatically metabolized drugs. Guidelines are provided under Dosing, above.

179.9 THERAPEUTIC SUPPORT OF ANIMALS WITH CANCER

In order that pets maintain the highest quality of life, and that chemotherapy dosages be maintained at the highest level, the veterinarian should, whenever possible, use prophylactic strategies to circumvent common toxicities.

179.9.1 Antiemetics

The recent introduction of serotonin antagonists such as ondansetron (Zofran) and dolasetron (Anzemet) has markedly altered toxicity patterns for animals treated with many drugs. Vomiting and nausea, leading to inappetence and weight loss, are common after treatment with drugs such as cisplatin (in dogs) and doxorubicin (in cats and dogs). Anzemet, given intravenously once at a dosage of 0.5 to 1 mg/kg or given orally once 20 to 30 minutes prior to treatment may markedly reduce the risk of this toxicity.

179.9.2 Appetite Stimulants

Anorexia is a common side effect of chemotherapy in cats (particularly doxorubicin or vincristine). Cyproheptadine (Periactin; 0.35 to 1 mg/kg given orally in cats and 0.1 to 0.2 mg/kg given orally in dogs) may stimulate appetite. The drug may be dosed every 12 hours, or less frequently if inappetence is mild. Megestrol acetate is an effective appetite stimulant in cats at a dosage of 0.25 to 0.5 mg/kg per day given orally for 3 to 5 days, then every 2 to 3 days. In humans, megestrol acetate not only improves appetite but also enhances the enjoyment of food.

Vincristine may result in intestinal ileus in cats and less commonly in dogs. Prokinetic drugs such as metoclopramide may act to reverse this toxicity. Some practitioners recommend prophylactic use of metoclopramide to reduce the risk of inappetence caused by vincristine or doxorubicin (perhaps by central action to reduce nausea). For prophylactic purposes, treatment is started at the time of chemotherapy and continued for 4 to 5 days. Prior to administering strong emetogens (e.g., cisplatin), owners should withhold food, because this reduces the risk of vomiting and may prevent future “aversion” to that food.

179.9.3 Antidiarrheal Drugs

The pet's diet should remain as stable as possible during chemotherapy to avoid exacerbation of gastrointestinal damage. Prophylactic absorbents (e.g., Kaopectate) may reduce the risk of diarrhea. If diarrhea occurs, a bland diet should be offered; if the diarrhea persists, and causes such as parasitism in these often immunosuppressed patients have been eliminated, sulfasalazine or metronidazole may reduce the severity. Prophylactic trimethoprim-sulpha (TMPS) antibiotics should be considered (see below).

179.9.4 Urothelial Bladder Wall Protection

Cyclophosphamide and ifosfamide are hepatically metabolized to their active forms and also to compounds that can cause bladder wall damage (acrolein). Prolonged contact time between the bladder wall and acrolein results in hemorrhagic cystitis. Furosemide, given as a single dosage (2 mg/kg either IV or PO) at the time of cyclophosphamide administration, almost completely abrogates this toxicity and is recommended even in dogs receiving prednisone concurrently. Allowing ample opportunity for the dog to void urine is equally important, and cyclophosphamide is preferably administered in the morning rather than late in the day. Mesna is a thiol drug that is active only in urine; it binds to acrolein, preventing the toxicity of urothelial damage. Because mesna is expensive, its use usually is limited to dogs receiving ifosfamide that have a high risk of urothelial damage.

Treatment of hemorrhagic cystitis includes the use of anti-inflammatory drugs (e.g., piroxicam, 0.3 mg/kg given orally once a day); with prolonged cases, intravesicular dimethyl sulfoxide (DMSO) may accelerate recovery. Most cases resolve with time, but because the condition may require several weeks to subside, it is a toxicity best prevented. Sterile hemorrhagic cystitis is extremely rare in cats.

179.9.5 Prevention of Neutropenic Sepsis

Neutropenia is a common side effect of many chemotherapeutics and may occasionally be severe (e.g., neutrophil count less than 500/μL at the nadir). The risk of sepsis is low in animals receiving antibiotics concurrently, because the nadir rarely persists longer than a couple of days. Many oncologists recommend prophylactic use of a broad-spectrum, oral antibiotic (e.g., TMPS) in animals receiving a myelosuppressive agent for the first time. If the nadir is greater than 1000/μL, subsequent administrations may be given without prophylactic antibiotics.

Administration of TMPS to dogs for 14 days from the day of treatment with doxorubicin markedly reduced the likelihood of gastrointestinal toxicity (vomiting or diarrhea), hospitalization, and reduced quality of life (Karnovsky score). These effects, most marked in dogs with lymphoma, may be due to reduced bacterial translocation in damaged intestinal epithelial layers.

When a pet is severely neutropenic, it is tempting to use recombinant granulocyte-colony stimulating factor (G-CSF). Neutropenic dogs should have high endogenous G-CSF and are unlikely to benefit from exogenous administration. Also, the available human recombinant product (hr-G-CSF [Neupogen, Amgen]) carries a risk of induction of neutralizing and cross-reacting antibodies. Appropriate use of hr-G-CSF would be in cases in which an inadvertent and potentially lethal chemotherapy overdose has been delivered. For such a patient, hr-G-CSF therapy from the time of chemotherapy administration to beyond the neutrophil nadir has the best chance of preventing sepsis and death.

179.10 SPECIFIC CHEMOTHERAPEUTIC AGENTS

179.10.1 Commonly Used Alkylating Agents

Commonly used alkylating agents are listed in Table 179-1. Cyclophosphamide (Cytoxan) is used primarily for the treatment of lymphoma in dogs and cats. Chlorambucil (Leukeran) is used primarily for the treatment of chronic lymphocytic leukemia or low-grade lymphoma in dogs and cats and as a substitute for

cyclophosphamide if hemorrhagic cystitis occurs. Melphalan (Alkeran) is used primarily in combination with prednisone for the treatment of multiple myeloma in dogs and cats.

179.10.2 Less Commonly Used Alkylating Agents

Less commonly used alkylating agents are listed in Table 179-1. Mechlorethamine (Mustargen) is used in the MOPP protocol for lymphoma in dogs and cats. Procarbazine (Matulane) is used in the MOPP protocol for lymphoma in dogs and cats. Dacarbazine (DTIC) is used in combination with doxorubicin for the treatment of lymphoma, and some anecdotal activity has been indicated for melanoma. Lomustine (CCNU, Ceenu) is used for the treatment of lymphoma, mast cell tumors, brain tumors (response in gliomas and meningiomas) and possibly histiocytosis. Ifosfamide (Ifex) is active against lymphoma and soft tissue sarcomas, particularly in cats.

179.11 ANTITUMOR ANTIBIOTICS

Antitumor drugs act by interfering with topoisomerases, deoxy-ribonucleic acid (DNA) intercalation, and other mechanisms. These drugs usually exhibit cross-resistance with others in their class and with drugs in other classes, such as vincristine, paclitaxel, and etoposide. This resistance is mediated by the MDR glycoprotein.

179.11.1 Commonly Used Antibiotics

Commonly used antibiotics are listed in Table 179-2. Doxorubicin (Adriamycin; generic form) is the most active single agent in the treatment of lymphoma in dogs and is highly effective in combinations for lymphoma treatment in dogs and cats. It has broad-spectrum efficacy in the treatment of solid tumors, particularly osteosarcoma, and in combination with cyclophosphamide. Low-dose doxorubicin may be used for "sensitization" of tumor cells to radiation therapy. Mitoxantrone (Novantrone) shows moderate efficacy against lymphoma in dogs but low efficacy in cats. It also has low efficacy in the treatment of carcinomas and sarcomas. However, in combination with radiation therapy it may be efficacious for oral squamous cell carcinoma (SCC) in cats and in combination with piroxicam for transitional cell carcinoma in dogs. Dactinomycin (Actinomycin-D, Cosmegen) is a low-cost alternative to doxorubicin for canine lymphoma. However, it has low efficacy in the treatment of carcinomas and sarcomas.

Table • 179-1 Commonly Used Alkylating Agents

DRUG	FORM	POTENTIAL SIDE EFFECTS	REGIMEN
Cyclophosphamide (Cytoxan)	25, 50 mg tablets; 500 mg vials	Myelosuppression	250 mg/m^2 PO
		Hemorrhagic cystitis	200 mg/m^2 IV q3wk
			50 mg/m^2 PO every other day
Chlorambucil (Leukeran)	2 mg tablets (refrigerate)	Mild myelosuppression	2–8 mg/m^2 PO every other day
			14 mg/m^{2}PO daily for 4 days q3wk
Melphalan (Alkeran)	2 mg tablets (refrigerate)	Myelosuppression	1.5 mg/m^2 PO daily for 10 days, then a 10-day "rest"
Less Commonly Used Alkylating Agents			
Mechlorethamine (Mustargen)	10 mg vials	Myelosuppression	In MOPP: 3 mg/m^2 IV weekly
		Extravasation reaction	
Procarbazine (Matulane)	50 mg capsules	Nausea, anorexia, diarrhea	In MOPP: 50 mg/m^2 PO daily (dogs); 10 mg/cat PO daily
		Myelosuppression	
Dacarbazine (DTIC)	200 mg vials	Myelosuppression	800 mg/m^2 q3-4wk
		Anorexia, vomiting, diarrhea (Anzemet is used prior to treatment.)	
Lomustine (CCNU; Ceenu)	10, 40, and 100 mg capsules	Myelosuppression, neutropenia, and delayed thrombocytopenia in dogs; delayed neutropenia in cats	70–90 mg/m^{2}PO q4-6wk (dogs)
		Irreversible renal and liver toxicity (uncommon)	50 mg/m^2 PO q6wk (cats)
Ifosfamide (Ifex)	1 g with mesna (1 g) vials	Myelosuppression	375 mg/m^2 IV (dogs)
		Hemorrhagic cystitis (must be given with mesna and diuresis protocol)	900 mg/m^2 IV (cats)
			Given q3wk in 0.9%
		Renal toxicity in cats	NaCl with mesna

179.11.2 Less Commonly Used Antibiotic

Bleomycin (Blenoxane) is a less commonly used antitumor antibiotic (Table 179-2). Its possible efficacy in the treatment of squamous cell carcinoma and lymphoma is unproven.

179.12 PLATINUMS

Cisplatin (Platinol) has efficacy in the treatment of canine osteosarcoma and many carcinomas. It is not for use in cats. Carboplatin (Paraplatin) has efficacy similar to cisplatin with no apparent renal toxicity (Table 179-3).

179.12 ENZYME

The enzyme L-asparaginase is used primarily for lymphoma in dogs (Table 179-4).

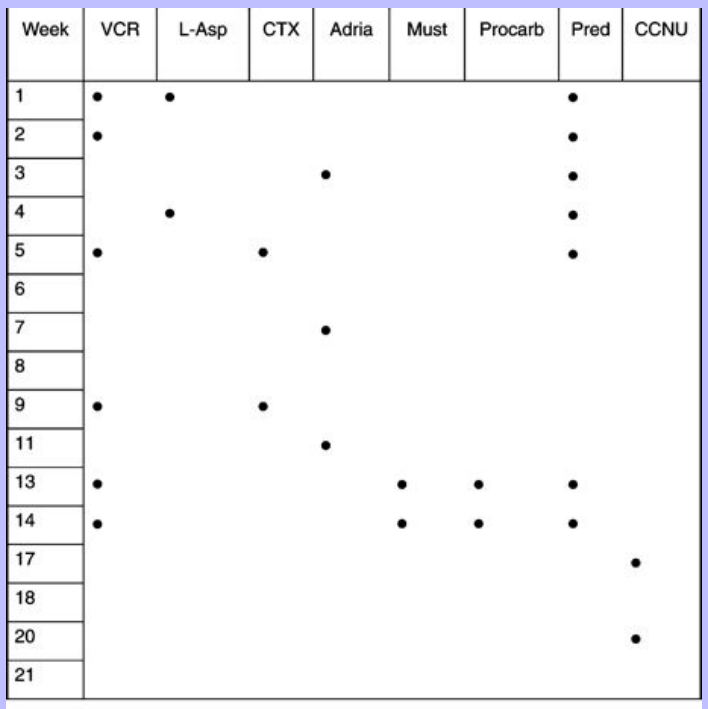
718

719

Table • 179-2 Commonly Used Antibiotics

DRUG	FORM	POTENTIAL SIDE EFFECTS	REGIMEN
Doxorubicin, (Adriamycin; generic)	200 mg	Myelosuppression	30 mg/m^2 IV (large dogs)
		Cumulative cardiotoxicity	25 mg/m^2 or 1 mg/kg IV (cats and small dogs)
		Anorexia, vomiting, diarrhea	
		Allergic reaction (infusion rate should not exceed 2 mg/min)	Given q2-3wk
		Possible renal toxicity in cats	
		Extravasation reaction	
Mitoxantrone (Novantrone)	20 mg	Myelosuppression	6 mg/m^2 IV (dogs)
		GI effects (uncommon)	6.5 mg/m^2 IV (cats)
			Given q3wk
Dactinomycin (Actinomycin-D, Cosmegen)	0.5 mg (extravascular) vials	Myelosuppression	0.7–1 mg/m^2 IV (not used in cats to date)
		Diarrhea, vomiting	
		Requires slow infusion rate	Given q3wk
		Extravasation reaction	
Less Commonly Used Antibiotic			
Bleomycin (Blenoxane)	15 IU (15 mg) vials	In humans: allergic reaction, pulmonary fibrosis	0.3–0.5 IU/kg IV or SQ weekly

Figure 179-1 Tufts VELCAP-SC protocol for treatment of lymphoma in dogs. Patients are induced over 11 weeks with a combination of vincristine (0.75 mg/m^2 IV), L-asparaginase (10,000 IU/m^2 SQ, maximum dose 10,000 IU), doxorubicin (<1 m^2 = 1 mg/kg IV, >1 m^2 = 30 mg/m^2 IV), cyclophosphamide (250 mg/m^2 PO), and a tapering dose of prednisone starting at 40 mg/m^2 PO daily. All dogs in complete remission (CR) at week 13 receive consolidation treatments of MOPP (mechlorethamine [3 mg/m^2 IV], vincristine [0.75 mg/m^2 IV], procarbazine [50 mg/m^2 PO once a day for 14 days], and prednisone [40 mg/m^2 PO once a day for 14 days]) at weeks 13 and 14, followed by CCNU (90 mg/m^2 PO) at weeks 17 and 20. The protocol is reinstituted if clinical relapse is noted. The total cumulative dosage of doxorubicin should not exceed 180 mg/m^2. Dogs that are in CR by week 21 discontinue chemotherapy. Dogs receiving cyclophosphamide are treated concurrently with furosemide, 2 mg/kg PO once.



VCR = vincristine, L-Asp = L-asparaginase, CTX = cyclophosphamide, Adria = doxorubicin, Must = mechlorethamine, Procarb = procarbazine, Pred = prednisone.

Table • 179-3 Platinums Used as Chemotherapeutic Agents

DRUG	FORM	POTENTIAL SIDE EFFECTS	REGIMEN
Cisplatin (Platinol)	50 mg (aqueous) vials	Renal toxicity Vomiting and (less commonly) diarrhea Myelosuppression Fatal pulmonary edema in cats	50–70 mg/m^2 IV with 0.9% saline diuresis q3-4wk
Carboplatin (Paraplatin)	50 mg, 150 mg vials	Myelosuppression	250–300 mg/m^2 IV q3-4wk

Table • 179-4 Enzyme Used as a Chemotherapeutic Agent

DRUG	FORM		REGIMEN
L-asparaginase (Elspar)	10,000 IU vials	Anaphylaxis	10,000 IU/m^2 SQ or IM weekly

Table • 179-5 Commonly Used Mitotic Inhibitors

DRUG	FORM	POTENTIAL SIDE EFFECTS	REGIMEN
Vincristine (Oncovin; generic)	1 mg vials	Mild myelosuppression (dose related) Anorexia in cats, rarely dogs (dose related) Peripheral neuropathy (rare) Extravasation reaction	0.5–0.75 mg/m^2 IV weekly
Vinblastine (Velban)	10 mg vials	Myelosuppression Peripheral neuropathy (very rare) Extravasation reaction	2–2.5 mg/m^2 IV weekly

179.14 MITOTIC INHIBITORS

Mitotic inhibitors act to inhibit assembly (vinca alkaloids) or disassembly (paclitaxel) of the mitotic spindle. Paclitaxel is rarely used in veterinary medicine, and dosages have not been published.

The commonly used mitotic inhibitor vincristine (Oncovin; generic form) is curative for canine transmissible venereal tumor. It also is very effective in combination chemotherapy for lymphoma in dogs and cats. It is included in some combinations for the treatment of sarcomas. Vinblastine (Velban) is effective in combination chemotherapy against lymphoma in dogs and cats; however, it is seldom used because of its myelosuppressive effect, which makes it more problematic than vincristine to include with other drugs. Vinblastine also appears to have efficacy for mast cell tumors in dogs (Table 179-5).

180 CHAPTER • 180 Practical Radiation Therapy

Alain P. Théon

Radiation therapy is the use of ionizing radiation for local and regional treatment of patients with malignant tumors and, occasionally, selected benign diseases. In veterinary medicine, it is a consultative discipline in which veterinary radiation oncologists see animals referred by other veterinarians. The objective of radiation therapy is eradication of a tumor with preservation of normal tissue structure and function.

The availability of appropriate equipment and the evolution of veterinary oncology into a multidisciplinary specialty have led to an increasingly important role for radiation therapy in the management of cancer in small animals. New developments in radiation therapy technology permit treatment of arbitrary tumor volumes anywhere in the body. Radiation therapy can be used alone or in combination with surgery or chemotherapy. The increase in the use of radiation therapy has led to a progressive decrease in the need for radical surgery as the sole treatment for many common cancers.

180.1 BIOLOGIC PRINCIPLES OF RADIATION THERAPY

180.1.1 Biological Effect of Radiation

The radiation used in radiation therapy is called *ionizing radiation* because it is sufficiently energetic to cause ionization and excitation of atoms and molecules in cells, resulting in a variety of short-lived ions and chemically unstable free radicals that cause molecular damage. With therapeutic radiation doses, the molecular damage most detrimental to cell survival is that involving the structure and function of genomic deoxyribonucleic acid (DNA).[1] Most of the damage to DNA results indirectly from interaction of DNA with free radicals derived from the ionization of cellular water molecules, the most common molecule in cells. Ionizing radiation produces many types of DNA damage, including single-strand breaks (SSB), double-strand breaks (DSB), base damage, and DNA-DNA or DNA-protein crosslinks. During the processing and enzymatic repair of the damage or during DNA replication, DNA damage may be completely repaired or may become irreversible. Radiation repair is usually more efficient in normal cells than in tumor cells. Although the majority of DNA damage can be repaired, heterologous DNA double-strand breaks are most often irreparable. Irreversible damage to the DNA results in chromosomal aberrations, gene mutations, cell degeneration, and cell death.

At clinically achievable doses, the damage induced by radiation results in cell death or terminal growth arrest.[2] Depending on the cell type and numbers and the kind of DNA damage, cell death occurs through two distinct pathways, proliferative cell death (mitotic cell death) and programmed cell death (apoptosis).[3] Mitotic cell death is the main form of cell death induced by ionizing radiation. It occurs during postirradiation mitosis in proliferating cells entering mitosis with unrepaired DNA damage. Mitotic cell death is selective for cells engaged in the mitotic cycle. This form of cell death is particularly relevant to radiotherapy of tumors, because one of the most important characteristics of a tumor is its ability to divide indefinitely. The difference in proliferative activity in normal cells and tumor cells accounts in part for the selective cytotoxic effects of radiation against tumors. Mitotic cell death is not immediate, but rather occurs after the cell passes through one or more consecutive aberrant mitoses, during which the number of chromosomal aberrations and genomic dysfunctions increases, leading to metabolic failure and cell death.[1] This mechanism of cell death leads to cell necrosis and results in local inflammation.

Cell death through apoptosis is a normal, noninflammatory physiologic process that occurs spontaneously or in response to cellular stress, including ionizing radiation. Apoptosis occurs regardless of the cell cycle and does not require cell division. Susceptibility to radiation-induced apoptosis is cell type specific and is most prominent in hematopoietic or lymphoid cells, but not in stromal-or epithelial-derived tissues. Apoptosis requires intact cellular mechanisms that are often compromised in tumor cells. The tumor suppressor gene protein p53 plays a pivotal role in radiation-induced apoptosis. Its mutation, which is common in some cancers, results in a decreased contribution from apoptosis to the overall cell death in different cell types.

While mitotic cell death and apoptosis kill and eliminate cancer cells, radiation-induced terminal growth arrest irreversibly prevents further tumor evolution. Terminal growth arrest is a process similar to senescence in which the cells remain physiologically active but have lost their ability to proliferate. This cytostatic effect on tumor cells results in a delayed tumor response to irradiation.

180.1.2 Tissue Response

The degree and speed of tumor regression after therapeutic irradiation is determined by several factors, including the susceptibility to ionizing radiation related to tumor type and the contribution of inhibition of cell proliferation and cell death; tumor cell kinetics (i.e., the rate of cellular proliferation, cell death, and cell loss); the proportion of clonogenic cells; and the amount of vasculoconnective tissue in or around the tumor.[4]

Tumor response during or shortly after treatment is not a reliable index of tumor curability, but slow regression of a tumor type that usually regresses quickly is often associated with an unfavorable prognosis. Tumors that regress quickly and completely (e.g., mast cell tumors in dogs and oral squamous cell carcinomas in cats) may also recur quickly. Incomplete tumor regression at the completion of treatment does not necessarily indicate treatment failure. Some soft tissue sarcomas, meningiomas, and pituitary adenomas may remain detectable for weeks or even months after the course of radiotherapy is finished and yet ultimately disappear and never recur. Tumor disappearance may also be delayed when bony changes associated with bone invasion are present. Anatomic deformity caused by tumors with an abundant intercellular stroma may be slow to resolve, which may be interpreted as a treatment failure. Slowly regressing oral epulides in dogs are in fact one of the few highly curable tumors with radiation therapy. A practical implication of the complex reasons for different rates of tumor response is that only persistent or continual growth is a reliable sign of treatment failure. Therefore, as long as a tumor is regressing after radiotherapy, biopsy is contraindicated. A prematurely positive result from a biopsy specimen may lead to unnecessary salvage surgery, and repeated biopsies interfere with the healing of normal tissues.

721

722

The effects of radiation on normal tissues are restricted to the treatment site. Chronologically, the clinical effects of irradiation are subdivided into *acute effects,* which occur during or immediately after treatment (during the first 3 months) and *late effects,* which occur months to years after completion of treatment. The rate of appearance of injury depends not only on the proliferative activity of the stem cells but also on the lifetime of the differentiating progeny of these cells.

Acute effects result primarily from radiation-induced stem cell depletion, which exceeds cell production in actively proliferating parenchymal tissues. The most common acute radiation reactions involve the skin and mucous membranes and result from stem cell proliferation that is inadequate to maintain the epithelial surface. The acute effects of radiation therapy always accompany curative radiotherapy, because to some extent they mirror the damage done to tumor tissue. Although acute effects may be temporarily painful and require supportive therapy, they are not complications but normal tissue reactions, which are usually self-limited and resolve naturally after treatment. Acute reactions of the skin (skin desquamation and epilation) and oral mucosa

(mucositis) may be lessened by cleansing the tissue with a 1:1 solution of hydrogen peroxide and normal saline and using topical ointments, systemic antibiotics, and corticosteroids to minimize infection and inflammation.[5]

Table • 180-1 Role of Radiation Therapy in the Treatment of Specific Neoplastic Diseases

ANATOMIC SITE	ROLE OF RADIOTHERAPY	RESULTS	ACUTE REACTIONS	COMPLICATIONS
Skin and Subcutaneous Tissues				
Squamous cell carcinoma	Curative treatment alternative to surgery for carcinomas not invading bone; treatment of choice for lesions of eyelids and nasal plane in cats and over cartilage; performed preoperatively for advanced tumors; palliative treatment with modest increase in survival for carcinoma of nasal plane in dogs.	*Nasal plane in cats:* 2-yr LCR: 77% for lesions <2 cm; 37% for advanced lesions[16]; comparable results for tumors of pinnae and forehead.	Erythema, moist desquamation, epilation; rarely, ulceration	Permanent epilation, skin atrophy, subcutaneous fibrosis; rarely, soft tissue necrosis
Mast cell tumor (dogs)	Primary treatment for small lesions; used postoperatively for microscopic or gross residual disease; adjuvant postoperative treatment for completely resected grade II/III lesions; preoperative treatment for unresectable tumors; low histologic grade and location on an extremity are favorable prognostic factors; used in combination with surgery and chemotherapy in dogs with regional metastasis.	2-yr LCR: 70%-92% for postoperative microscopic disease; 50%-85% for lesions <2 cm; 20%-58% for large tumor and gross residual tumor[11,12,36]; 60% for postoperative locoregional irradiation for node-positive dogs.[37]	Same as for squamous cell carcinoma	Same as for squamous cell carcinoma

	Soft tissue sarcomas	For operable tumors: postoperative treatment when risk of surgical complication exists due to tumor size or location; preoperative treatment when increased risk of radiation complications exists due to radiosensitive normal tissue (brain, spinal cord, lung, guts) in treatment field. For advanced inoperable lesions: primary treatment followed by limited resection if lesion rendered operable.	*Dogs:* 2-yr LCR: 33% for primary radiotherapy of all histologic types and sizes[15]; 40%-50% for hemangiopericytoma (HPA)[18,38] and 30% for fibrosarcoma (FSA)[18] after subtotal resection; 85% for postoperative radiotherapy of all histologic types; 76% for FSA and 100% for HPA after microscopically incomplete resection[18]; 40 months median survival for postoperative irradiation of infiltrative lipomas.[39] *Cats with cutaneous FSA at vaccination sites:* 2-yr LCR: 55% with preoperative treatment,[29] 30% with postoperative treatment.[40]	Same as for squamous cell carcinoma	Same as for squamous cell carcinoma
	Perianal gland	Postoperative treatment for adenocarcinomas and regional irradiation to local lymph nodes for high-risk or node-positive dogs; primary treatment for large adenomas.	Median survival: 12–18 months for perianal adenomas/carcinomas with postoperative irradiation.[41,42]	Same as for squamous cell carcinoma ADD: diarrhea and bleeding	Same as for squamous cell carcinoma ADD: Stenosis
	Head and Neck				

	Oral cavity	*Dogs:* Curative radiotherapy for small, caudally located squamous cell carcinoma (SCC), mycosis fungoides (MF), fibrosarcoma (FSA) of the gingiva/palate, buccal mucosa; alternative to surgery for small, rostrally located SCC, plasmacytoma of the gingiva/palate and floor of the mouth, and epulides; used postoperatively for advanced resectable SCC and FSA; used alone or with chemo-therapy to improve survival for advanced unresectable lesions; palliative for advanced melanomas (MMA) and tumors of the base of the tongue and tonsils. *Cats:* Curative for odontogenic tumors and epulis; palliative for SCC with modest increase in survival.	*Dogs:* 2-yr LCR for lesions <2 cm : 100% for epulides; 74% for SCC; 67% for FSA; 54% for MMA[25]; comparable results for postoperative treatment of advanced resectable (2–4 cm) epulides, SCC, and FSA. Prolongs survival in advanced SCC (median survival, 7.5 months) and FSA (median survival, 7.1 months); palliative for symptoms of advanced MMA (median survival, 7–8 months).[14,23] *Cats:* 2-yr LCR : 100% for postoperative irradiation of odontogenic tumors.[43]	Painful mucositis, resulting in dysphagia, xerostomia, and weight loss	Persistent xerostomia, dental decay; rarely, fistulas, bone exposure, and osteoradio-necrosis of mandible and maxilla
	Nasal cavity/paranasal sinuses	Primary treatment to improve survival for carcinomas and sarcomas; combination with surgery or chemotherapy may not increase survival. Curative alone or in combination with chemotherapy for localized lymphoma.	*Dogs:* Median survival for nonlymphoproliferative tumors: 10–13 months (all tumors)[17,44]; 12–14 months for carcinomas[14,45]; 15 months for chondro-sarcomas.[14] *Cats:* Median survival for nonlymphoproliferative tumors: 12 months (all tumors)[46]; 28 months for lymphoma.[47]	Nasal and oral mucositis; conjunctivitis ± keratitis for eye in radiation field; skin epilation	Loss of smell, chronic keratitis, cataract, kerato-conjunctivitis; rarely, bone necrosis
	Ear canal	Primary treatment alternative to surgery for small ceruminous adenocarcinoma or squamous cell carcinomas; used postoperatively for advanced lesions.	2-yr LCR: 56%[48]	Otitis, dysphagia	Damage to middle and inner ear and cranial nerves syndrome)

Thyroid	*Dogs:* Irradiation used alone or as a postoperative treatment with subtotal resection of adenocarcinomas; used preoperatively for inoperable lesions, followed by limited resection if lesion is rendered operable. *Cats:* Primary treatment with radioiodine for functional adenomas and adeno-carcinomas; used as postoperative treatment with subtotal resection for carcinomas.	*Dogs with carcinomas treated with teletherapy:* 2-yr survival rate: 50% after irradiation alone[49]; 66% after subtotal resection in dogs with no evidence of metastasis.[50] *Cats treated with radioiodine:* 2-yr cure rate for adenomas: 92%[51]; >50% for carcinomas given postoperative treatment.[52]	Teletherapy: Skin epilation, dysphagia (esophagitis), hoarseness, cough (tracheitis)	Teletherapy: Subcutaneous fibrosis; rarely, spinal cord damage
Central Nervous System				
Pituitary gland	Effective in controlling signs of mass effects, in dogs with macroadenoma/carcinomas and no/mild neurologic signs; used in combination with medical treatment for pituitary-dependent hyperadrenocorticism (PDH). Ineffective for dogs with severe neurologic signs.	*Dogs with Cushing's disease:* 2-yr survival: No neurologic signs, 100%[53]; mild to moderate neurologic signs, 45%[54]; median survival in dogs with severe neurologic signs, 4 months.[54] *Cats with acromegaly:* Median survival, 15 months [55,56]	Hair loss, skin erythema, otitis, dullness (brain edema)	Hearing loss, cataract formation if eye is in the field; rarely, brain necrosis
Intracranial meningioma	Postoperative irradiation after incomplete resection for cure and primary radiation therapy (RT) for inoperable lesions.	Postoperative irradiation 2-yr LCR: 70%[20]; median survival in dogs with inoperable tumors: 9 months.[34]	Exacerbation of neurologic signs dullness	Somnolence, Seizure, behavioral modification, local motor or sensory signs
Spinal cord	Postoperative treatment to improve neurologic signs and survival.	Median survival for postoperative irradiation of meningiomas: 17 months.[57]	Subtle exacerbation of Neurologic signs	Decrease in sensa-tion or motor weakness pain; rarely, irreversible spinal cord myelopathy
Bone				

Primary bone tumors	For appendicular osteosarcomas: preoperative treatment combined with chemotherapy (cisplatin/carboplatin) for limb-sparing procedure; palliative treatment as alternative to amputation or for pain relief in advanced disease. For axial and skull tumors: postoperative irradiation concurrent with chemotherapy.	Median survival of dogs with osteosarcoma (OSA) treated with limb-sparing surgery, irradiation, and cisplatin: 9 months[33]; treated with irradiation and cisplatin: 5 months[34]; treated with palliative irradiation alone: 2–4 months.[58]	Skin erythema, dry/moist desquamation	Subcutaneous fibrosis, ankylosis, distal edema; rarely, bone/soft tissue necrosis
Metastatic bone tumors	Palliative local treatment or systemic administration of bone-seeking radioisotopes for pain relief.	Mean survival in dogs treated with radioactive Sm-153: 8 months.[9]	Depression of platelet and white blood cell count	
The local control rate (LCR) is provided as a cure rate; the median survival or local control is provided if a cure rate has not been determined or if it cannot be computed because of small sample size.				

Late effects are considered complications of radiation therapy. They are caused primarily by damage to the vasculoconnective stroma and slowly proliferating parenchymal tissues, such as the kidneys, cartilage, bone, or lungs. Clinically, radiation complications appear to be less severe in cats than in dogs. In cats, feline immunodeficiency virus (FIV) infection may be associated with a higher risk of radiation complications. Unlike acute effects, radiation complications are not self-limited and tend to be progressive. They are usually irreversible. In practice, with appropriate treatment techniques, the risk of severe complications is low and should be weighed against the probability of tumor control.[6] Radiation complications are usually managed conservatively. Occasionally, severe complications, including chronic ulcers, radionecrosis of soft tissues or bone, intestinal or rectal stenosis, or cystitis may require surgical resection of the involved tissue or organ (Table 180-1).

722

725

180.1.3 Radiocurability

The radiation doses delivered and the volume of tissue treated in clinical radiotherapy are determined as much by the tolerance of normal tissue that is included in the irradiated volume as they are by the tumor being treated. Normal tissue in the radiation field is said to be dose limiting with respect to the maximum dose that can be safely administered. Therefore tumors are typically treated within a narrow range of doses, thus commonly achieving a narrow range of tumor control rates. Maximal doses are therefore limited even for tumors with high local failure rates. This is true in spite of the fact that one can confidently assume that a sufficient dose of radiation will control virtually any localized tumor. Thus a radiocurable tumor is one that can be eradicated by a dose of radiation that is well tolerated by the surrounding normal tissues. A practical implication of this is that a tumor that is curable in one anatomic site may not be curable in another. The art of clinical radiotherapy is to find the right balance between tumor control and injury to normal tissues, to achieve what is called *uncomplicated cure*. A curative dose of radiation is a dose that will potentially cure or control the disease and result in a probability of serious complications of less than 5% for bone or soft tissue necrosis and less than 1% for spinal cord injury.

Because curative radiation doses are often by necessity close to the maximum dose tolerated by normal tissues, the radiation dose must be planned and delivered accurately to the tumor with as little radiation dose to the uninvolved normal structures as possible. Accurate tumor localization with modern imaging technology

(computed tomography [CT] and magnetic resonance imaging [MRI]) and optimum use of the radiation therapy techniques allow delivery of a high radiation dose to the tumor relative to the surrounding normal tissue. The choice of a treatment technique depends on the location, size, and extension of the tumor and adjacent normal structures. Each technique exploits the specific differences in patterns of dose distribution in tissues according to the type (photons versus electrons) and energy of radiation and the distance from the source of radiation to the lesion to be treated.

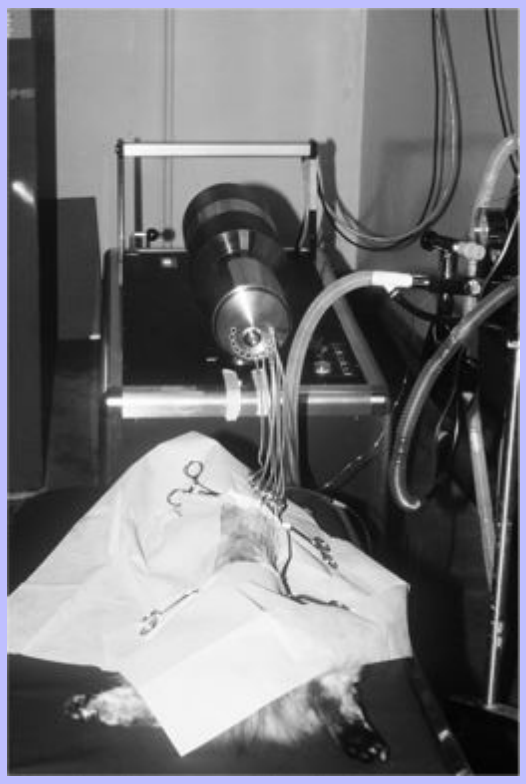
In *teletherapy* (also called *external beam therapy*), the distance between the source of radiation and the patient (50 to 100 cm) allows delivery of a relatively uniform dose of radiation to a large volume of tissue. The higher the energy of the radiation, the more significant the sparing of superficial structures (skin and subcutaneous tissues) and the greater the penetration of the beam. Medium energy x-rays (200 to 300 kV) produced by orthovoltage units are useful for the treatment of superficial tumors because their limited penetration in tissue minimizes the radiation dose to deeper, uninvolved tissues. High energy radiation (greater than 1 MV [1 MV = 1 million electron-volt]), including x-rays produced by linear accelerators and gamma rays produced by telecobalt units, are used for the treatment of large and deep-seated tumors. The availability of high energy radiation therapy units in veterinary medicine has expanded the number and types of cancers that can be cured with irradiation. High energy electrons produced by a linear accelerator have a tissue penetration range of a few centimeters, which allows complete sparing of the underlying tissues. Electron beams are useful in the treatment of superficially located tumors or those overlying radiosensitive normal tissue (spinal cord, brain, lung, and gastrointestinal tract).

Brachytherapy is a technique in which sealed radioactive sources are applied directly to the area to be treated. The short distance between the source of irradiation and the tumor provides a rapid decrease in dose as distance from the radiation source increases. This allows delivery of a high radiation dose to the tumor-bearing structures while sparing uninvolved adjacent normal tissues. When radioactive sources (usually iridium-192) are implanted directly into the tissues (Figure 180-1), the technique is called *interstitial brachytherapy* or *curietherapy*. It is used for small lesions that cannot be completely excised and for operable cutaneous tumors with indistinct margins for which there is a high probability of recurrence.[7] It may also be used in combination with teletherapy to boost the radiation dose to a specific area. When radioactive sources (usually strontium-90) are applied to the tumor's surface (Figure 180-2), the technique is called *surface brachytherapy* or *plesiotherapy*. Treatment is curative for superficial lesions of the skin, including carcinoma in situ and early squamous cell carcinoma (SCC) lesions less than 2 mm thick. Surface brachytherapy may also be used as primary or ancillary treatment for superficial fibrovascular infiltrates of the cornea that are not responsive to medical treatment. The shortest distance between the radiation source and the tumor cells is achieved by use of organ-seeking radiopharmaceuticals that are administered systemically. Irradiation is then selective to the tissue that concentrates the radioisotope. Clinical applications of systemic radiotherapy include radioactive iodine-131 for the treatment of feline hyperthyroidism and functional thyroid cancer in dogs and cats; phosphorus-32 for myeloproliferative and lymphoproliferative diseases, such as polycythemia vera and essential thrombocythemia[8]; and samarium-153 or strontium-89 for metastatic bone tumors.[9]

Another way to achieve uncomplicated cure with radiation therapy is to divide the dose into a series of equal-sized fractions given over several weeks, a process called *fractionation*. Fractionated irradiation allows selective regeneration of normal tissues due to their greater ability to repair radiation injury between treatments and to repopulate during the course of radiotherapy relative to the majority of tumors. As a result, curative treatment may be given while not exceeding the tolerance of the surrounding normal tissues. Clinical data, essentially in people, indicate that large doses per fraction are preferentially damaging to slowly proliferating tissues responsible for radiation complications. As a rule, when the dose of radiation per fraction decreases, the

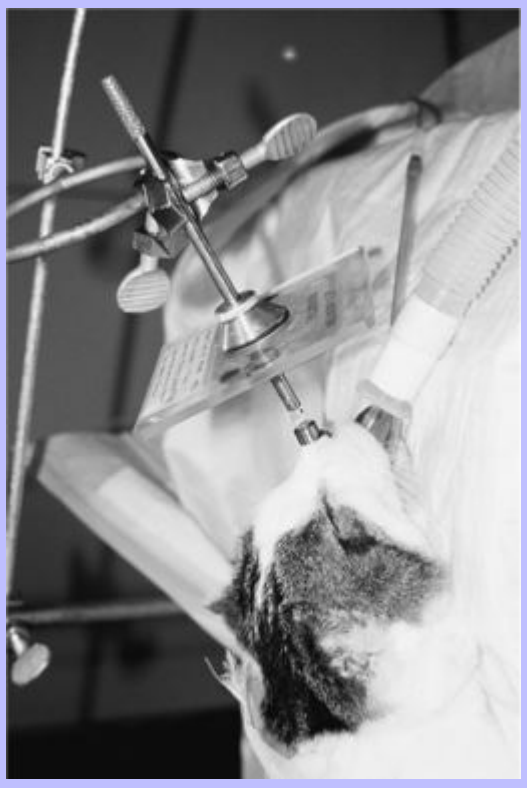
risk of radiation complications decreases, which allows the use of higher total doses and inclusion of a larger volume of normal tissues.

Figure 180-1 Setup for interstitial brachytherapy using a remote afterloader for postoperative irradiation of an interscapular fibrosarcoma in a cat. The technique is ideal for this location because a high radiation dose can be delivered, yet dose-limiting normal tissue, including the spinal cord and lungs, is spared. The treatment is done on an outpatient basis and poses no radiation hazard to personnel. The head of the remote after-loader (Gammamed Iii; RTS Technology, North Andover, Massachusetts), which contains a radioactive source (10 Ci, iridium-192) in a shielded container, is connected by source guide tubes to plastic needles implanted in the tumor bed below the skin. After all personnel have left the treatment room, the afterloader is activated from a shielded control room, and the radioactive source is driven through the array of applicators to deliver the planned dose. When treatment is complete, the radioactive source returns to the shielded container, and personnel can safely enter the treatment room.



In people, the standard fractionation for external beam therapy includes daily (5 days a week) dose fractions of 1.8 to 2.0 Gy (Gray [1 Gy=100 rad]). In teletherapy, various treatment schedules have evolved over the years, with dose fractions decreasing from 4 Gy given on an alternate-day schedule (Monday-Wednesday-Friday) to 3 Gy given on a daily schedule (5 days a week), and total radiation doses have increased from 40 to 60 Gy. The current recommendation for curative treatment is delivery of daily radiation doses (5 days a week) of 3 Gy or less in an overall treatment time that is as short as is consistent with acute reactions (over 3 to 4 weeks). Longer overall treatment times or intertreatment times (three fractions/week) increase the risk of "tumor escape" through accelerated repopulation. The benefit of daily treatment compared with alternate-day treatments has been shown in cats with oral carcinomas[10] and dogs with mast cell tumors.[11] In addition, in people, treatment prolongation caused by interruptions due to severe acute reactions, intercurrent illness, public holidays, or machine breakdown has been shown to have a negative influence on the outcome. The detrimental effect of treatment interruptions increases as treatment progresses. An early interruption in the treatment course is less detrimental for the patient than a late interruption.

Figure 180-2 Cat undergoing surface brachytherapy for early-stage squamous cell carcinoma of the nasal plane. The strontium-90 radioactive source at the tip of the applicator is a fission byproduct (half-life, 30 years) that produces an electron beam (2.3 MeV maximum energy). Electrons have shallow penetration in tissues, which allows delivery of high radiation doses to the tumor without exposure to the underlying normal tissues. The dose is 100% at the surface and decreases rapidly with depth: 40% at 1 mm, 20% at 2 mm, and less than 1% at the surface of the nasal cartilage. The applicator is carefully positioned directly on the surface of the lesion. The Lucite shield protects the operator's hands from scattered electrons. Because each treatment takes 3 to 4 minutes, the applicator is held with a stand to minimize radiation exposure to personnel. The surface dose ranges from 200 to 250 Gy. Usually one treatment is sufficient.



Because brachytherapy is used to treat smaller target volumes and the volume irradiated outside the target volume is minimized, the potential for complications is lower than with teletherapy. As a result, dose

fractionation with large doses per fraction may be used for interstitial brachytherapy (five doses of 5 to 7.5 Gy given once a week) or plesiotherapy (one or two doses of 150 to 200 Gy) without increasing the risk of serious complications.

180.2 CLINICAL RADIATION THERAPY

The basic principle of clinical radiation therapy is that treatment should always benefit the patient, even though the treatment outcome may not be entirely predictable. The selection of patients for radiation therapy should involve consultation with a radiation oncologist, preferably in a multidisciplinary clinic setting, and should include consideration of all aspects of the individual patient. The only contraindication for radiation therapy in dogs and cats is inability to tolerate the multiple episodes of anesthesia necessary for positioning and immobilization during treatment. Concurrent disease, particularly of the heart and liver, may be more limiting to survival than cancer.

726 727

180.2.1 Treatment Goals

After the extent (staging) and pathologic characteristics of the tumor have been evaluated, the objective of radiation therapy must be determined based on the likelihood of tumor spread, the expected cure rate, and treatment morbidity. The treat-ment goal should be defined at the onset of formulation of the therapeutic strategy, because it affects the selection of the appropriate treatment modalities (irradiation alone or in combination with other modalities) and the radiation treatment plan (technique and target volume). A correct assessment of the treatment goal is one of the most important decisions in radiation therapy. Overly aggressive treatment plans can expose animals that are not curable to needless morbidity, prolonged and expensive treatment, and unnecessary radiation effects. On the other hand, therapeutic decisions that are too pessimistic deprive the animal of a small but real chance for cure.

180.2.1.1 Curative Radiotherapy

Radiation therapy is most commonly used with curative intent when there is no evidence of widespread dissemination of metastases. Animals are treated with curative intent when it is expected that a finite probability exists that the tumor will be destroyed after adequate therapy, even if that chance is low. Radiation therapy given with curative intent is called *definitive therapy* if it is used for a localized, primary tumor that has been biopsied or incompletely resected. Radiation therapy is called *adjuvant therapy* if it is applied to a primary tumor or to sites of potential spread when the malignant cell burden is microscopic or below the level detectable by current imaging methods. Local and regional tumor control is an absolute necessity for cure of a patient with a solid tumor. *Tumor control* refers to complete eradication of the tumor at the primary site and in adjacent involved tissues and lymphatics. Failure to achieve control results in an increased likelihood of metastases and death. Tumors that are diagnosed and treated at an early stage, before distant metastases have occurred, are often curable by radiation therapy. Tumors arising from or involving organs highly vulnerable to radiation injury and tumors with a high propensity to develop distant metastases are rarely cured with radiation therapy alone.

The probability of tumor control depends on several clinical factors, including the tumor's size, extent, histologic grade, proliferative activity, and location and whether there is a history of previous treatment. Other factors, such as the patient's species, gender, age, and performance status, also may affect tumor control. One of the most important factors influencing the probability of local control is the tumor's size and extent. An inverse relationship between the probability of local control and tumor volume has been shown for mast cell tumors,[12] oral tumors (squamous cell carcinomas, fibrosarcomas, melanomas, and

epulides),[13,14] and soft tissue sarcomas[15] in dogs; squamous cell carcinomas of the nasal plane in cats[16]; and intranasal tumors (carcinomas, chondrosarcomas) in dogs.[17] Although invasion of bone or cartilage is not a contraindication to irradiation, local control rates are higher when the tumor is confined to the site of origin.

Histologic identification and grading of tumors are useful pretreatment predictors of biologic behavior. In practice, some tumors (e.g., round cell tumors) are easily controlled with low radiation doses, but most of the common tumors that can be cured with radiation (carcinomas, soft tissue sarcomas) require high doses. A few tumor types (e.g., glial tumors) are rarely cured, even with high doses. Usually, microscopic tumor deposits of any histologic type can be cured with moderate doses of radiation.[18] Histologic grading and tumor cell kinetics have been shown to be prognostic factors. High histologic grades are associated with a poorer prognosis after irradiation for mast cell tumors[12] and soft tissue sarcomas.[19] A high tumor growth fraction is associated with a poorer prognosis for SCC of the nasal plane, meningiomas in dogs, and oral SCC in cats.[10,16,20]

Tumors of similar histologic types arising from different anatomic sites have different biologic characteristics. In some instances, cancers arising from sites only 1 or 2 cm apart show markedly different responses that are not explainable by current knowledge. For example, in cats, squamous cell carcinoma of the facial skin is curable with radiation therapy alone, but squamous cell carcinoma of the oral cavity is rarely controlled. Paradoxically, in dogs, squamous cell carcinoma of the oral cavity is radiocurable, but squamous cell carcinoma of the nasal plane cannot be controlled with irradiation.

180.2.1.2 Palliative Radiotherapy

The goal of palliation is to relieve pain or other complications resulting from an incurable tumor but not to prolong life. Although life may be prolonged through the use of palliative irradiation, this is not the primary goal. For pets with extensive and rapidly progressive tumors and anticipated short survival, radiation therapy may be used to slow local progression of the disease and relieve distressing symptoms. Palliative radiation therapy offers an opportunity for rapid improvement in the quality of a pet's life. In this setting, the treatment course is as short as possible, using a few larger dose fractions and lower total doses. However, the use of large dose fractions is associated with a high risk of complications, and palliative treatment regimens should not be used for animals with a life expectancy greater than 6 to 12 months. Administration of palliative versus curative treatment for purposes other than alleviating pain or suffering amounts to substandard care. Palliation is acceptable for animals with a short life expectancy because the probability of developing late complications is limited. Palliative irradiation is not a less expensive, less complicated alternative treatment for pets that would benefit from treatment given with curative intent. The use of palliative radiation therapy has been investigated for management of selected tumors, including thyroid tumors,[21] pituitary tumors,[22] oral melanomas,[23] and nasal tumors[24] in dogs and oral squamous cell carcinomas in cats.[25] Tumor control duration has proved to be inferior compared with that obtained with standard fractionation and is associated with significant risk of complications in animals surviving longer than 6 months.

Palliative radiation therapy is useful to relieve discomfort associated with both skeletal tumors (primary and metastatic bone lesions) and soft tissue tumors. Pain, compression of vital structures such as the brain, ulcerating skin lesions, and bone tumors or bone metastases in weight-bearing bones susceptible to fracture can be managed effectively with palliative radiation. Dogs with appendicular osteosarcomas that are not candidates for amputation may benefit from palliative radiation therapy. Treatment consists of three to four weekly large-dose fractions (8 to 10 Gy). Pain relief occurs in 75% to 90% of these dogs, with the period of pain control lasting 2 to 3 months.[26,27] The duration of pain relief may be slightly longer for appendicular

than for axial bone tumors and may be increased by use of higher radiation doses and concurrent use of platinum-based chemotherapy.[26,27]

727

728

180.2.2 Clinical Role of Radiation Therapy

Ideally, the radiation oncologist should be involved at the time of diagnosis and initial decision making so that if and when radiation therapy is used, the oncologist will be knowledgeable about all the factors involved in the treatment planning. Seeing the intact, untouched lesion before surgery can be of immense help in planning definitive treatment. The best results are achieved by an initial integrated treatment plan with combined modalities tailored to the particular pet's cancer rather than by ad hoc attempts to salvage the failures of another modality. Treatment of localized tumors often involves the use of surgery or radiation therapy or a combination of the two (Figure 180-3). Treatment of tumors with a high probability or evidence of metastasis at the time of diagnosis involves a combination of local treatment and systemic chemotherapy.

180.2.2.1 Primary Radiation Therapy

Radiation therapy plays an important role in the curative treatment of small malignant solid tumors. It is also used in the management of benign tumors, including adenomas of the pituitary and perianal glands and oral epulides in dogs and thyroid adenomas in cats. Surgery is essentially a local treatment, whereas radiotherapy offers locoregional treatment covering a wider area, less constrained by anatomic boundaries and surgical techniques. Local control rates for radiation therapy are equivalent to those for surgery for small, localized tumors (2 to 4 cm) in many sites, and irradiation has the advantage of controlling the disease in situ, thus avoiding disruption of anatomic structure and preserving function. In practice, radiation therapy is used for lesions that are technically difficult to completely resect without excessive functional and cosmetic mutilation. Radiation therapy is particularly well suited for lesions of the facial skin, including carcinomas of the nose, eyelids, ear canals, or pinnae, and certain more extensive lesions of the forehead and cheeks. Radiation therapy may be preferred at specific sites on the trunk or extremities for tumors that have extended near or around critical structures such as the spinal cord, nerves, large vessels, or tendons. For certain early-stage lesions in less strategic locations, surgery can be carried out expediently and effectively and therefore is preferred. For example, surgery is preferred for oral tumors that are rostrally located, where a wide excision is possible. Radiation therapy is preferred, on the other hand, for caudally located tumors when a high risk of oral incompetence is anticipated after radical excision or when regional lymph node involvement is observed or anticipated.

Less frequently, primary radiotherapy is used for tumors that are highly radiocurable or that are technically unresectable. Tumors of any size, including transmissible venereal tumors at all sites, localized mycosis fungoides of the oral mucosa in dogs, and extranodal solitary lymphomas (stage I), can be cured with radiation therapy alone. Radiation therapy is the mainstay of treatment for central nervous system (CNS) and intranasal tumors because most such lesions are inoperable.

Radiation therapy is also used as primary treatment for control of invasive and inoperable cancers. The goal is not to cure the pet, because extensive disease or potential distant metastases obviate this goal, but to prolong survival. This setting is different from palliative radiation therapy, in which the quality, rather than the duration, of survival is of utmost importance. Many animals may live for long periods in comfort with residual tumor or metastasis. Some animals have good prospects of prolonged survival with inoperable regional disease without demonstrable metastases. The goal of radiation therapy in this situation is to achieve lasting local control and improve the duration and quality of survival. Here, control indicates that the local disease can be kept within bounds for extended periods. In dogs with large intracranial tumors (gliomas,

pituitary adenomas, meningiomas) or inoperable soft tissue sarcomas, the treatment goal is to control the growth of the tumor and extend the dog's survival. Thus the radiation therapy technique and dose are similar to those used in curative radiation therapy.

Reirradiation of recurrent tumors that are unresectable because of their strategic location may be used in selected cases to prolong survival.[28] Because of the poor radiation tolerance of previously irradiated adjacent normal tissues, recurrences are best managed by resection.

Combinations of surgery and radiation therapy may be used for advanced locoregional disease.

Radiation therapy and surgery may be “equally” beneficial for the treatment of small lesions, but they also can be mutually beneficial in the treatment of advanced tumors. The goals of a combined approach are to preserve function and cosmetic appearance and to reduce the chance of local failure when the probability of cure by either modality alone is low.

The timing and dose of radiotherapy and its sequencing with surgery depend on (1) the tumor's resectability (preoperative irradiation may be used if complete resection is not feasible); (2) the dose desired (high doses must follow surgery); and (3) the extent of the planned surgery (extensive procedures must precede radiotherapy). The interval between the application of each treatment method should be planned to minimize additive complications without losing any advantage in tumor control.

The main combinations of surgery and radiation therapy involve preoperative and postoperative radiation therapy. The optimal sequencing depends on the tumor's size, location, and histologic characteristics. The best interval between preoperative radiation and surgery or between surgery and postoperative radiation has not been clearly established. When radiation therapy is given preoperatively, the optimal interval between irradiation and surgery is usually 3 to 4 weeks. This allows acute radiation reactions to resolve before fibrosis begins to develop. When radiation therapy is given postoperatively, an interval of 2 to 3 weeks after surgery usually allows satisfactory wound healing.

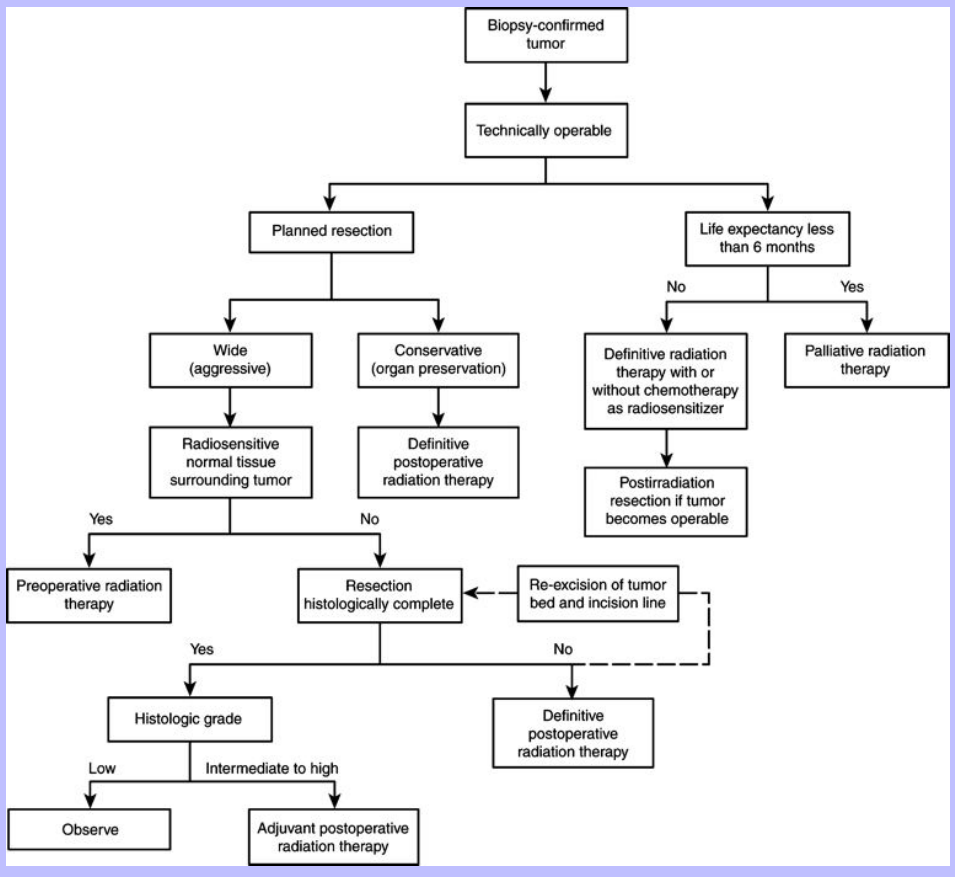
180.2.2.1.1 Postoperative radiation therapy.

Radiation therapy may be used postoperatively as an adjuvant treatment for control of postoperative microscopic disease or with curative intent for control of residual gross disease. The advantages of postoperative irradiation are that the entire surgical specimen is available for review for exact histopathologic classification; the extent of microscopic tumor can be assessed directly; and a high dose of radiation can be given without increasing surgical morbidity. In wounds that are healing poorly, such as those with postoperative infection or dehiscence, irradiation will further hinder healing. In pressing instances, irradiation may be given to animals with an open wound. Depending on the size of the wound, this may be accomplished without complication; however, the wound may have difficulty healing by secondary intention and may require skin grafting or plastic reconstructive techniques.

Adjuvant radiation therapy is used to improve local control and functional results for treatment of operable tumors. A tumor is considered operable if it is anticipated to be highly likely that all gross disease can be resected, leaving at most microscopic disease. Operable tumors include accessible, medium-sized or advanced tumors in locations where wide resection is possible. Adjuvant radiation therapy is used to improve local control and functional results. In this setting, clinically apparent disease is surgically resected and irradiation is given to eliminate tumor microextension present at the periphery of the gross tumor and in regional lymph nodes. In clinical practice, animals with resectable tumors are treated with postoperative irradiation when histopathologic evidence of microscopic residual disease is

present (close to or positive for tumor at surgical margins) or when the risk of local recurrence is high after surgery because of extensive tumor invasion and high histologic grade. Clean surgical margins are not a guarantee that all tumor cells have been removed, because cell aggregates greater than $10^6/cm^3$ or higher are required for histopathologic detection. Aggressive intermediate or high-grade fibrosarcomas, hemangiopericytomas, cutaneous hemangiosarcomas, infiltrative lipomas and liposarcomas, myxosarcomas, synovial cell sarcomas, and mast cell tumors resected with clean surgical margins benefit from adjuvant postoperative irradiation.

Figure 180-3 Integration of radiation therapy in the management of solid tumors in patients with no evidence of systemic disease. The term *definitive radiation therapy (RT)* refers to therapy given at full dose when gross disease is present; *adjuvant RT* refers to radiation therapy given at moderate dose for treatment of microscopic or subclinical disease.



Unfortunately, radiation therapy is too frequently used after a partial resection in which gross residual disease is present. This is the setting in which the treatment combination is the least effective. Irradiation is most effective for treatment of microscopic or subclinical residual disease.[18] Partial removal of gross

disease (surgical debulking) provides little therapeutic advantage. For example, a surgical excision that removes 99% of a tumor containing 10^{10} cells (about 10 g of tissue) leaves 10^{8} tumors cells. In fact, subtotal resection may lessen the chance of cure by irradiation in some situations, because tumor cells may be disseminated throughout the surgical bed and may be implanted in relatively hypoxic scar tissue, where they are less sensitive to irradiation. In addition, reduction of tumor volume may result in a compensatory burst of accelerated regrowth of residual tumor cells, which can decrease the efficacy of radiation therapy.

180.2.2.1.2 Preoperative irradiation

Advantages of preoperative radiation are that it can eradicate subclinical or microscopic disease beyond the margins of the surgical resection; it may theoretically diminish tumor implantation within the operative field; and it can decrease the potential for dissemination of tumor cells that might produce distant metastases. In some cases it may convert a nonresectable tumor into one that can be resected.

Preoperative irradiation is more “dose effective” than postoperative radiotherapy; that is, a lower dose is needed preoperatively to reduce rates of local recurrence to the same extent as postoperative radiation. Although radiation doses are lower and radiation treatment fields are smaller than those used with postoperative radiation therapy, preoperative treatment may be associated with an increased risk of surgical morbidity. The decision to accept increased short-term morbidity from wound healing complications with preoperative radiation therapy must be balanced against the potential effects of larger radiation doses and larger treatment volumes associated with postoperative radiotherapy. Practical measures have proved useful in avoiding treatment complications. At the time of surgery, it is extremely important to handle irradiated tissues with care. Whenever possible, the fascia and underlying muscle should be left attached to the skin and subcutaneous tissue as they are reflected from the tumor. Potential dead spaces should be avoided, and wounds should be drained and closed without tension. Seromas and hematomas should be drained, because they are likely to increase the incidence of late wound breakdown and subsequent infection, thus delaying the administration of radiation therapy.

For large operable tumors with anticipated extensive regional microextensions or for those that arise from or are located close to radiosensitive normal tissue (brain, spinal cord, lung, abdominal cavity), there is an advantage in using adjuvant preoperative irradiation. In contrast to postoperative irradiation, preoperative treatment can be given to a smaller treatment volume with lower radiation doses. Although there is a potential increase in postoperative morbidity, the risk of long-term, radiation-induced complications is reduced. In this setting, irradiation is followed by wide-margin surgical resection according to the original extent of the disease. This treatment combination is effective for most operable cutaneous soft tissue sarcomas in dogs and cats. The benefit of this approach has been demonstrated for the treatment of feline fibrosarcomas at vaccination sites overlying the spinal cord and lungs.[29]

180.2.2.1.3 Sequential combination of surgery and radiation therapy.

A subset of animals with advanced, incompletely resectable cancer may be treated with definitive irradiation followed by surgery if the tumor undergoes significant regression and becomes resectable. In this setting, the timing between irradiation and surgery is longer (8 to 10 weeks) to allow tumor shrinkage and normal tissue recovery than in planned preoperative irradiation. This approach requires careful monitoring of tumor response after irradiation while planning the surgery. This treatment combination is different from that in which surgery is used for attempted salvage of those that experience a locoregional recurrence after definitive irradiation.

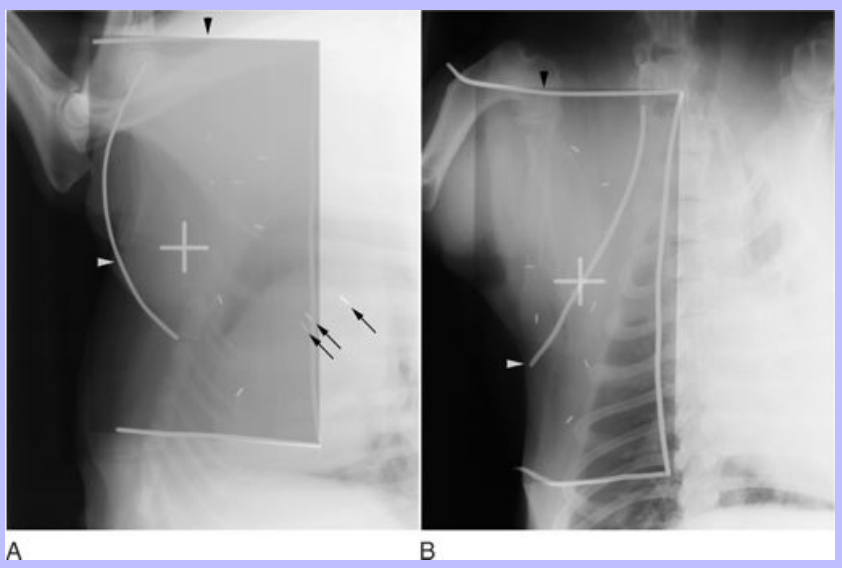
In clinical practice, the sequential combination of irradiation followed by surgery is reserved for situations in which either the tumor is initially thought to be unresectable or the original boundaries are obscured. In this setting, a definitive dose of radiation is used, followed by limited surgical resection to eliminate the residual gross disease that has not been sterilized by irradiation. This approach has been found effective, with minimal surgical morbidity in expert hands, for advanced lesions arising from the head (carcinomas and soft tissue sarcomas of the face and oral cavity) and neck region (thyroid carcinomas) and the extremities (fibrosarcomas, hemangiopericytomas, and mast cell tumors).

180.2.2.1.4 Surgical procedures helpful for radiation therapy.

Because the most common treatment combination is irradiation given after surgery, the surgeon plays a critical role in treatment. Unless the primary tumor can be removed in *toto*, it usually is preferable to perform a biopsy of the site, visualize the extent of the tumor, and then end the procedure. The treatment options can then be reconsidered. This approach is better than performing heroic surgical procedures that will compromise the efficacy of radiation therapy. Because the radiation treatment field must incorporate all areas that have potentially been contaminated by surgical dissection, single incisions, rather than multibranched ones, should be made. Drain sites should be positioned close to the wound to be included in the treatment field. Good communication between the radiation oncologist and the surgeon is imperative. Information regarding the total extent of tissue involvement, the estimated volume of residual tumor, and the quality of the surgical margins is required for radiation treatment planning. To excise the tumor and then refer the pet for radiation therapy treatment imposes a severe handicap on the therapist and the pet. The location of the cutaneous surgical scar, the palpable postoperative indura-tion, the owner's recollection, and the surgical notes are usually inadequate to determine the location of the tumor bed. Radiation treatment fields devised primarily on the location of the skin incision are associated with a risk of geographic treatment miss. For the radiation dose to be delivered precisely to the tumor confines, as identified at the surgical procedure, the walls of the excision cavity must be marked with radiopaque markers (i.e., steel or titanium surgical hemostatic clips or wire) to document the boundaries of the tumor bed and residual disease.

Radiographic documentation of the clips is used to localize the entire tumor volume for treatment planning and to verify that the treatment setup provides adequate coverage of the entire tumor volume (Figure 180-4). If markers are not present for guidance, the radiation oncologist must use larger than usual fields to decrease the likelihood of inadequate coverage, with subsequent increased risk of complications.

Figure 180-4 Dog with a mast cell tumor in the axillary region treated postoperatively with two orthogonal radiation fields: **A,** Lateral view. **B,** Dorsoventral view. The tumor bed is defined by radiopaque surgical hemostatic clips. The clinical setup was based on the location of the scar and surgical induration, the surgeon's recollection of the tumor location, and the surgical report, which provided anatomic landmarks (rib number) and measurements of tumor extension. Postoperative portal films were done to verify the treatment setup. The radiation fields marked with solder wire *(black arrowhead)* taped on the skin were determined clinically (*X* at center of treatment field). Although the skin incision was made almost directly over the tumor, the location of the skin incision marked with solder wire *(white arrowhead)* was not immediately above the tumor because the position of the underlying tissues was different on the treatment table than that on the operating table. The dorsoventral radiation field **(B)** was barely adequate. The lateral field **(A)** was clearly inadequate because surgical clips *(black arrows)* extended outside the dorsal border of the radiation field. Correction of the treatment setup would not have been possible without demarcation of the tumor volume with surgical clips. The geographic treatment miss would have resulted in tumor recurrence.



Integration of Radiation Therapy, Surgery, and Chemotherapy for Inoperable or Metastatic Disease

The use of combinations of radiation therapy and chemotherapy has increased. Radiation therapy alone or in combination with surgery is usually directed at primary tumor masses and involved regional nodes, whereas systemic treatment is aimed at distant metastases.

Radiation therapy and chemotherapy play important roles in the management of metastases that are either documented (radiographically, histopathologically, or cytologically) or suspected (subclinical disease). Radiation therapy is effective for the treatment of subclinical disease in the regional lymphatics and in the treatment of clinically positive lymph nodes. For tumors with a high potential for regional spread (invasive tumors with intermediate to high histologic grades), a large treatment field is used to include the first-echelon lymph nodes along with the primary lesion. The benefit of large-field irradiation can be demonstrated by the lower rate of metastasis observed in dogs with malignant oral tumors treated with irradiation when compared with dogs treated with surgery.[14] When clinically positive nodes are present, the radiation field includes the gross disease (primary and positive nodes) and contiguous nodes that are at risk. In this setting, radiation therapy is often used with palliative intent.

Adjuvant chemotherapy is used for treatment of subclinical disease after effective local treatment (surgery and/or irradiation) has been completed. The initial decision to use local treatment alone or both a local and systemic approach depends on the risk of occult distant disease and the availability of effective chemotherapy. As local treatment becomes more effective, animals live longer and a higher number develop metastasis. This pattern of failure is seen with some tumors that previously had the reputation of low metastatic rates, including squamous cell carcinomas of the oral cavity, fibrosarcomas in any location, and hemangiopericytomas. As a result, chemotherapy may have a bigger part to play as an adjuvant to local treatment. Adjuvant chemotherapy with cisplatin, carboplatin, or doxorubicin is indicated for control of subclinical disease in tumors with a high risk of distant failure, including osteogenic sarcomas and high-grade soft tissue sarcomas. Preliminary data on the use of chemotherapy to prevent metastasis for oral melanoma[23] and mast cell tumors[30] in dogs and vaccine-associated sarcomas[29] and oral carcinomas[25] in cats have failed to show a therapeutic benefit.

For the treatment of locally advanced, unresectable disease, concomitant chemoradiotherapy is the most promising approach. Schedules of concomitant chemoradiotherapy can be synchronous, with the two modalities administered close together, or alternating, with the treatments administered in a nonoverlapping fashion. Administration of radiotherapy and chemotherapy concomitantly is a dose-intensive approach that exploits the independent, complementary activity of radiotherapy locally and chemotherapy distantly (spatial cooperation). In cats with mediastinal lymphoma and severe respiratory compromise secondary to pleural effusion, radiation therapy may be used along with induction chemotherapy to improve the likelihood of rapid and complete remission. The beneficial effects of concurrent chemotherapy and radiation therapy result from the added toxic effects of the two modalities in the treatment field, with less than additive effects against dose-limiting normal tissues. Cisplatin and carboplatin are ideal agents for concomitant chemoradiotherapy. They have established single-agent activity, as well as synergistic interaction but nonoverlapping toxicities with radiotherapy. The drugs may be used as a systemic cytotoxic agent in addition to irradiation or as a radiosensitizer administered as small, frequent doses systemically[31] or intratumorally.[32] Several clinical trials are underway to test the efficacy of irradiation combined with carboplatin and mitoxantrone for the treatment of advanced tumors in dogs and cats. The benefit of adding chemotherapy to irradiation has been shown with cisplatin in dogs

with appendicular osteosarcomas, regardless of whether they are resectable, and for carboplatin in dogs with intranasal carcinomas.[33–35]

180.3 ROLE OF RADIATION THERAPY IN THE MANAGEMENT OF CANCER PATIENTS

Radiation therapy can be used in the clinical management of virtually every type of solid tumor in dogs and cats. Table 180-1 outlines the role of radiotherapy for specific tumors, the results obtained, and the possible treatment complications that should be discussed with owners before treatment. This table is not intended for use as a manual of radiation therapy. Most of the results are given as local control rates at 2 years because in general, the risk of local failure 2 years after irradiation is low in animals that have survived disease free. As a result, the 2-year local control rate represents a reliable estimate of the cure rate in dogs and cats that have no evidence of metastasis before treatment. The local control rates given here represent a lower limit, because they were obtained with treatment protocols that may not have been optimum. It is anticipated that the current use of higher radiation doses given with effective fractionation schemes and optimum irradiation techniques will result in higher local control rates. Specific results according to tumor size, location, and other prognostic factors are given in the other chapters of this text.

A great improvement in the treatment of cancer could be achieved immediately if all animals received what is currently acknowledged as the best available treatment. This requires that individual veterinarians appreciate the potential of available treatment modalities, especially the advantage of multidisciplinary consultation, at the time of initial diagnosis and treatment.

The role of radiation therapy for the treatment of brain tumors and in combination with surgery for mammary and salivary gland adenocarcinomas, thymomas, and intra-abdominal carcinomas (prostate, bladder, and rectum) needs to be established in animals because of its important role in people.

181 CHAPTER • 181 Hematopoietic Tumors

David M. Vail

Douglas H. Thamm

181.1 LYMPHOMA

Lymphoma (lymphosarcoma [LSA]) is the most common hematopoietic tumor affecting dogs and cats. It is defined as a proliferation of malignant lymphoid cells affecting primarily the lymph nodes or solid visceral organs, such as the liver or spleen. The management of LSA initially is quite gratifying in both species, because response rates approach 90% in dogs and 70% in cats treated with multiagent chemotherapeutic approaches. Unfortunately, most animals eventually succumb to relapse of chemotherapy-resistant, disseminated disease.

181.1.1 Etiology

The etiology of LSA in companion animals is for the most part unknown. Although certain varieties of LSA in cats have been directly and indirectly associated with feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV), respectively, no strong evidence exists as yet of a retroviral etiology in dogs. A weak to moderate association between canine LSA and the use of herbicides, exposure to strong magnetic fields, or residence in industrial areas has been observed in preliminary epidemiologic studies,[1–5] and a recent study found a meaningful association between environmental tobacco smoke exposure and the risk of feline gastrointestinal LSA.[6] More thorough studies are necessary to evaluate these associations further. Both somatic and germ line mutations in the tumor suppressor gene p53 have been reported in some cases of canine LSA,[7] and occasional clustering of LSA in related dogs has suggested a heritable component in limited instances.[8]

181.1.2 Classification of Lymphoma

Various classification schemes for LSA have been evaluated, including those based on the anatomic site, the World Health Organization (WHO) clinical stage (Table 181-1), the histologic/cytologic phenotype, and the immunophenotype.

181.1.2.1 Canine Classification

In the dog, 80% to 85% of cases are the multicentric anatomic type and present as WHO stage III or IV.[9–13] Alimentary (~7%), cutaneous (~6%), mediastinal (~3%) and miscellaneous extranodal sites (central nervous system [CNS], bone, heart, nasal cavity, and primary ocular locations) are less frequently encountered. Regardless of the histologic classification scheme used (e.g., Kiel, NCI-Working Formulation), most cases (80%) equate to medium-or high-grade non-Hodgkin's LSA in humans.[14–16] Most canine LSA is of the B-cell immunophenotype, with approximately 20% to 30% being of T-cell derivation.[9,14–16]

Table • 181-1 World Health Organization Clinical Staging for Domestic Animals With Lymphoma

STAGE	CRITERIA
I	Single lymph node
II	Multiple lymph nodes in a regional area
III	Generalized lymphadenopathy
IV	Liver and/or spleen involvement (with or without stage III)
V	Bone marrow or blood involvement and/or any nonlymphoid organ (with or without stages I to IV)
Substage a	Without clinical signs of disease
Substage b	With clinical signs of disease

World Health Organization: TNM Classification of Tumors in Domestic Animals. World Health Organization, Geneva, 1980.

181.1.2.2 Feline Classification

In the cat, a definite and repeatable shift in anatomic type, immunophenotypic derivation, and retroviral associa-tion has occurred concomitant with the initiation of wide-spread FeLV testing and vaccination programs over the past 15 to 20 years.[17–19] Studies prior to this era reported that the mediastinal and multicentric forms of LSA predominated and that these represented younger, FeLV-positive cats. Contemporary reports document that currently, LSA primarily affects older, FeLV-negative cats and that the alimentary form predominates (Table 181-2). Only 10% to 20% of cases are now associated with FeLV antigenemia, compared with the 60% to 70% figure published before FeLV testing and vaccination became available.

Along with a shift away from FeLV antigen–associated tumors has come an alteration in the traditional signalment and relative distribution of anatomic sites. The median age of 9 to 10 years now reported is considerably higher than the 4-to 6-year medians reported prior to this era. The median age of cats within various anatomic tumor groupings has not changed, however, and sites traditionally associated with FeLV (i.e., mediastinal and multicentric locations) still occur primarily in younger, FeLV-antigenemic cats. Similarly, the alimentary form occurs most often in older, FeLV-negative cats. It is unclear whether this change in the epidemiology of LSA in cats is due to FeLV vaccination itself or whether the procedure of FeLV antigen testing before vaccination has allowed separation of potentially infective cats from the susceptible population. Either situation would result in a reduction in the number of FeLV-positive LSA cases. Recently, European oncologists have reported mediastinal LSA in young, Oriental breed cats that are uniformly FeLV negative.[19]

Table • 181-2 Characteristics of Feline Lymphoma by Anatomic Site

ANATOMIC SITE	RELATIVE FREQUENCY	AGE	T CELL ASSOCIATION	FeLV POSITIVE
Alimentary	50%-70%	~10–14 yr	High	Low (5%)
Multicentric	10%-25%	Depends on feline leukemia virus (FeLV) status*	Depends on FeLV status*	Approximately one third
Mediastinal/thymic	10%-20%	Young	High	High (>80%)
Nasal	~10%	Aged	Low	Low
Renal	5%-10%	Middle-aged	Low to moderate	Low to moderate
Other	5%-25%	Mixed	Mixed	Mixed

* FeLV-positive cats tend to be younger, and the cancer is more commonly of T cell derivation.

A distinct class of LSA in cats has more recently been reported.[20–23] This lesion, a granulated, round cell tumor, has been termed either *globule leukocyte tumor* or *large granular lymphocyte LSA,* although these are likely variations of the same disease. The tumor usually involves the intestinal tract and abdominal viscera, with systemic involvement being the norm. Affected cats are generally FeLV negative. A series of cats with LSA resembling human Hodgkin's disease also has been recently reported.[24]

181.1.3 Clinical Presentation and Signs

181.1.3.1 Canine Multicentric Lymphoma

LSA affects primarily middle-aged to older dogs. No sex predilection is observed, and many different breeds are represented. Only 10% to 20% of dogs are clinically ill (WHO substage b) at presentation,[9–13] therefore most cases present as healthy dogs with incidental generalized lymphadenopathy. In dogs with substage b disease, the clinical signs are nonspecific and can include inappetence, weight loss, and lethargy. Paraneoplastic hypercalcemia may result in presentation for polyuria and polydipsia. In stage V disease, if bone marrow involvement is marked, peripheral cytopenias may result in presentations reflecting neutropenic sepsis, thrombocytopenic hemorrhage, or anemia.

181.1.3.2 Canine Lymphoma of Other Sites

The presentation and associated clinical signs of LSA reflect the anatomic form present in each individual case. Alimentary forms present with signs specific to the gastrointestinal tract, including vomiting, diarrhea (with or without blood), weight loss, and inappetence. Mediastinal forms may present with respiratory signs, including dyspnea and muffled heart sounds. Mediastinal LSA may also present with precaval syndrome, characterized by pitting edema of the head, neck, and forelimbs secondary to tumor compression of the cranial vena cava (Figure 181-1). Nearly half of mediastinal LSA cases are associated with paraneoplastic hypercalcemia,[25] therefore polydipsia and polyuria are common presenting complaints for this anatomic form.

Cutaneous LSA has been called the “great imitator” because of its ability to present in many varying forms. Single or multiple cutaneous lesions can occur, which may appear as mild, eczematous plaques or more impressive nodular tumors (Figure 181-2).

Figure 181-1 Precaval syndrome in a dog with mediastinal lymphoma. Pitting edema of the head and neck are noted.

733

734

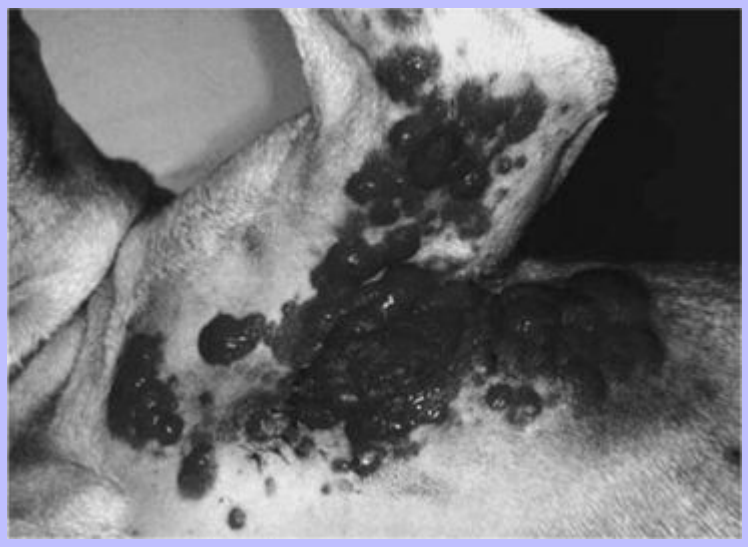
Lesions may or may not be pruritic and can occur anywhere on the skin and in the oral cavity.

Miscellaneous sites of disease result in signs attributable to the location (i.e., lameness for bone lesions, neurologic compromise for CNS lymphoma).

181.1.3.3 Feline Lymphoma

No breed or sex predilections have been identified. Age and its association with FeLV status have been discussed previously. In general, cats are more likely than dogs to present with clinical illness; 75% or more present with substage b signs.[17,18] The clinical presentation of LSA in cats depends on the anatomic sites involved. Cats with alimentary LSA or large granular lymphocyte LSA present with varying degrees of weight loss, unkempt haircoat, inappetence, chronic diarrhea, and vomiting. Cats with mediastinal disease are often in severe respiratory distress due to the effects of an intrathoracic mass or the presence of significant pleural effusion. Cats with renal LSA may present with polyuria/polydipsia secondary to renal failure. In the case of nasal LSA, sneezing, chronic serosanguineous nasal discharge, exophthalmos, and facial deformity are common presentations. Cats with FeLV-associated LSA are more likely to present with pale mucous membranes as a result of anemia.

Figure 181-2 Cutaneous T-cell lymphoma (mycosis fungoides) in a dog.



181.1.4 Diagnosis

181.1.4.1 Physical Examination

A thorough physical examination should include palpation of all assessable lymph nodes and a rectal examination in the dog. The clinician should inspect the mucous membranes for pallor or petechiae indicative of anemia or thrombocytopenia secondary to myelophthisis and should look for evidence of major organ failure, including the presence of icterus or uremic ulcers. Abdominal palpation may reveal organomegaly, intestinal wall thickening, or mesenteric lymphadenopathy. The presence of a mediastinal mass and/or pleural effusion may be suspected based on thoracic compression in cats and auscultation in both dogs and cats. An ophthalmic examination, including funduscopic assessment, may reveal abnormalities (e.g., uveitis, retinal hemorrhage, ocular infiltration) in approximately one third to one half of dogs with LSA.[26]

181.1.4.2 Hematologic Abnormalities

A complete blood count (CBC), including a numeric platelet count, is a necessary part of any evaluation of dogs or cats suspected of having LSA. Hematologic abnormalities occur in most cases of multicentric LSA.[27] Anemia, when present, is usually normocytic, normochromic, and nonregenerative, reflecting anemia of chronic disease. Regenerative anemias may reflect concomitant blood loss or hemolysis. Cats with FeLV-associated disease may have a macrocytic anemia. If significant myelophthisis is present, the anemia may be accompanied by thrombocytopenia and leukopenia. Circulating atypical lymphocytes may be indicative of bone marrow involvement and leukemia. It is important to differentiate multicentric LSA with bone marrow involvement (i.e., stage V disease) from primary lymphoblastic leukemia (discussed later in

this chapter), because these two diseases have entirely different prognoses. Hypoproteinemia is more commonly observed in animals with alimentary LSA.

Bone marrow aspiration cytology is recommended for staging because of the prognostic significance of marked marrow involvement; it is also recommended for cases in which LSA is suspected but has not yet been documented.

181.1.4.3 Serum Biochemical Abnormalities

The serum biochemical abnormalities seen in LSA often reflect the anatomic site involved. In addition, approximately 15% of dogs with LSA (40% of dogs with mediastinal involvement) are hypercalcemic, often owing to the ectopic production of parathyroid hormone–related peptide.[25,27,28] In cases of hypercalcemia of unknown origin, LSA should always be considered high on the differential disease list, and diagnostics directed at this possibility should be undertaken. In addition, the presence of hypercalcemia can serve as a marker for response to therapy. Elevations in blood urea nitrogen and serum creatinine can occur secondary to renal infiltration with tumor, hypercalcemic nephrosis, or dehydration. Liver-specific enzyme or bilirubin elevations may result from hepatic parenchymal infiltration. Serum globulin elevations, usually monoclonal, occur infrequently with B cell–derived LSA.

181.1.4.4 Retroviral Status

In the cat, retroviral screening (i.e., FeLV and FIV) is important from diagnostic, prognostic, and husbandry standpoints.

734

735

The relative frequency of FeLV associations is presented in Table 181-2.

181.1.4.5 Imaging

Imaging (radiographic, ultrasonographic, or computed tomography [CT]) may be important for diagnosis, especially in cases lacking peripheral lymphadenopathy. Imaging is equally important for clinical staging (i.e., determining the extent of disease), because results may significantly affect the overall prognosis and alter the caregiver's willingness to pursue therapy.

Abnormalities on thoracic radiographs are noted in approximately two thirds to three fourths of dogs with LSA[29,30]; these include one third with evidence of pulmonary infiltrates (Figure 181-3) and two thirds with thoracic lymphadenomegaly. It is important to note that 20% of dogs present with cranial mediastinal lymphadenopathy, which correlates negatively with both remission and survival duration.[29]

Abdominal radiographs or ultrasound may reveal evidence of sublumbar/mesenteric lymph node, spleen, or liver involvement in approximately 50% of dogs. Abdominal ultrasound is most important in cats when intestinal LSA is suspected.

Special studies, including contrast studies of the gastrointestinal tract, CT or myelographic studies of the central nervous system, and skeletal radiograpic/scintigraphy surveys are reserved for cases in which involvement of the appropriate anatomic site is suspected.

In the authors' practice, for the typical cases of canine multicentric LSA, imaging is limited to thoracic radiographs, because there is no prognostic difference between dogs with stage III and stage IV disease (i.e.,

liver/spleen involvement); however, the presence of cranial mediastinal lymphadenopathy is of prognostic significance.[29]

181.1.4.6 Cytologic and Histopathologic Diagnosis

Microscopic conformation of LSA is the cornerstone of diagnosis in both cats and dogs. Fine needle aspirate (FNA) cytologic assessment by a skilled clinical pathologist is often adequate to make a diagnosis of LSA in dogs; however, conclusive histologic conformation is the gold standard. The predominance of a homogenous population of immature lymphoid cells is suggestive of LSA (Figure 181-4), although small cell variants do exist. Avoidance of nodes draining reactive areas (e.g., submandibular nodes in the presence of periodontal disease) is recommended, because reactive hyperplasia may mask (or mimic) the true neoplastic condition.

Figure 181-3 Lateral thoracic radiographic projection of a dog illustrating interstitial pulmonary infiltration with tumor typical of lymphoma at this site.

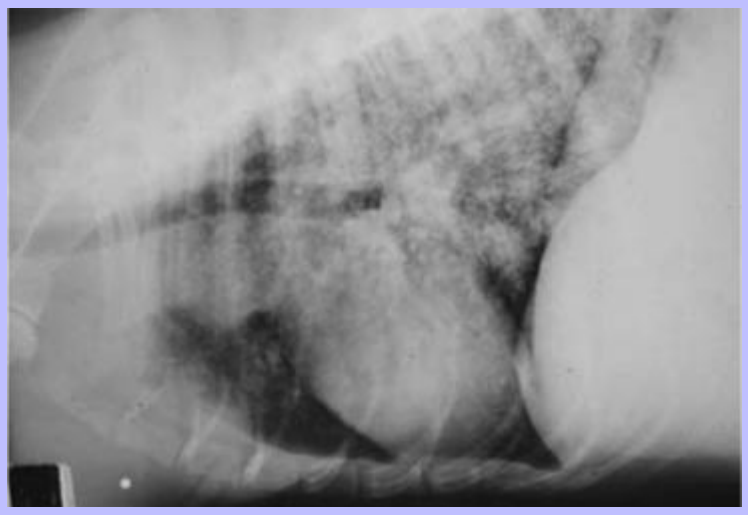


Figure 181-4 Fine needle aspirate cytology (Wright-Giemsa stain, ×1000) of a peripheral lymph node in a dog with high-grade lymphoma. The node is effaced with an homogenous population of immature lymphoid cells.

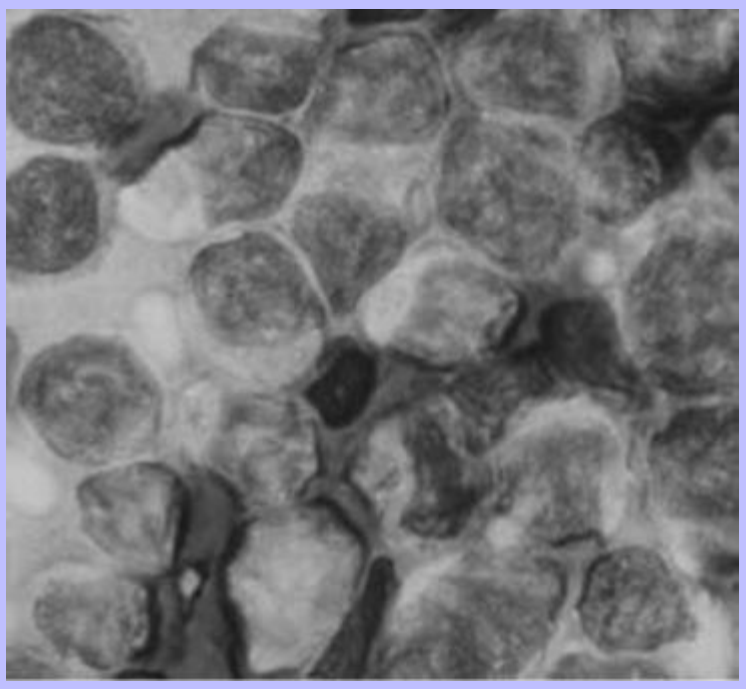


In the cat, FNA assessment alone is not sufficient in most cases because of the difficulties encountered in distinguishing LSA from benign hyperplastic lymph node syndromes unique to the species. These syndromes include idiopathic peripheral lymphadenopathy, plexiform vascularization of lymph nodes, and peripheral lymph node hyperplasia of young cats.[31–34] In these cases, whole lymph node excision is preferred, because evaluation of orientation, invasiveness, and architectural abnormalities may be necessary for diagnosis.

Besides their role in confirming a diagnosis of LSA, histologic and cytologic samples can be analyzed by various histochemical and immunohistochemical techniques to determine the immunophenotype (B cell versus T cell), tumor proliferation rates (e.g., Ki-67, proliferating cell nuclear antigen [PCNA], argyrophilic nucleolar organizer regions [AgNOR]), and histologic subtype (high-, intermediate-, or low-grade tumors).[9,15,16,35–38] The availability of such analysis is increasing; however, currently only immunophenotype in dogs is consistently predictive of prognosis. Histologic assessment of markers of multidrug resistance and apoptotic pathways (e.g., P-glycoprotein, p53) are currently being evaluated in dogs and cats with LSA, but their significance requires further evaluation.[7,37,39–43]

Additional site-specific cytologic or histologic assessments may be warranted when extranodal sites are suspected. Thoracocentesis followed by cytologic evaluation of pleural fluid is often diagnostic in cats with mediastinal LSA but is less likely to be of value in dogs with effusions secondary to mediastinal

involvement. Conversely, cerebrospinal fluid (CSF) analysis is more commonly helpful in dogs than cats with CNS LSA because the more common spinal form of LSA in cats is generally extradural.[44,45] In cats suspected of having CNS LSA, bone marrow and renal involvement are often present, and cytologic assessment of these organs is generally more easily attainable than CNS sites.

181.1.5 Differential Diagnosis

The differential diagnoses for LSA, which vary with the anatomic form of the disease, are presented in Table 181-3.

735

736

Table • 181-3 Common Differential Diagnoses for Lymphoma

ANATOMIC FORM	DIFFERENTIAL LIST
Generalized lymphadenopathy	•Disseminated infections (e.g., bacterial, viral, rickettsial, parasitic, and fungal) •Immune-mediated disorders (e.g., lupus, polyarthritis, vasculitis, dermatopathy) •Other hematopoietic tumors (e.g., leukemia, multiple myeloma, malignant or systemic histiocytosis) •Tumors metastatic to nodes •In cats, many benign reactive hyperplastic syndromes (see text)
Alimentary	•Infiltrative enteritis (e.g., lymphocytic, plasmacytic enteritis) •Nonlymphoid intestinal neoplasms •Granulomatous enteritis •Granulated round cell tumors in cats •Gastrointestinal mast cell tumors in cats
Cutaneous	•Infectious dermatitis (e.g., advanced pyoderma) •Immune-mediated dermatitis (e.g., pemphigus) •Other cutaneous neoplasms
Mediastinal	•Thymoma •Heart base tumor (chemodectoma) •Ectopic thyroid tumor •Pulmonary lymphomatoid granulomatosis •Granulomatous disease (e.g., hilar lymphadenopathy with blastomycosis)

181.1.6 Therapy

Untreated dogs and cats live an average of 4 to 6 weeks once a diagnosis has been established. In general, LSA is a systemic disease and requires a systemic approach to therapy (i.e., chemotherapy). Exceptions to this occur in cases of solitary site or extranodal LSA, for which local therapy involving either surgery or radiotherapy may be indicated.

181.1.6.1 Systemic Chemotherapy in Dogs with Lymphoma

There are almost as many chemotherapy protocols for dogs with LSA as there are veterinary oncologists. This likely reflects our inability to achieve cure in the majority of cases. LSA in the dog can be an initially gratifying disease to treat, because remission rates approach 80% to 90% with available combination chemotherapy protocols, and quality of life is generally excellent during the period of remission.[46] However,

the majority of dogs eventually succumb to drug-resistant recurrence of the disease, on average, 1 year after diagnosis.

Due to the large and ever increasing number of available chemotherapeutic protocols, several factors should be considered and discussed with caregivers when choosing a protocol, which can be done on a case-by-case basis. These factors include the cost, time commitment involved, efficacy, toxicity, and experience of the clinician with the protocols in question. With the availability of generic drugs, chemotherapy protocols are becoming affordable to a larger segment of veterinary clientele. In general, more complex combination chemotherapy protocols are more expensive, more time-consuming (i.e., requiring repeated office visits and closer monitoring), and more likely to result in toxicity than are simpler, single-agent protocols. However, as a general rule, more complex combination protocols result in longer remission and survival durations than do single agent protocols.

A complete listing of all available chemotherapy protocols for dogs with LSA is beyond the scope of this review, therefore the reader is referred to a recent review and other reports.[11,16,46] This discussion presents an example of the combination protocol used by the authors and the most widely used single agent protocol. Most complex combination protocols are modifications of CHOP protocols initially designed for human oncologic use. The CHOP protocol represents combinations of cyclophosphamide *(C),* doxorubicin (hydroxydaunorubicin *[H]*), vincristine (Oncovin *[O]*), and prednisone *(P)*. Regardless of which CHOP-based protocol is used, the overall median remission and survival times are approximately 8 and 12 months, respectively.[12,13,46,47] Approximately 20% to 25% of treated dogs are alive 2 years or longer after initiation of these protocols. Response rates and the length of response vary, depending on the presence or absence of prognostic factors discussed under Prognosis. Historically, the treatment protocol begins with an intensive *induction phase,* during which drugs are given weekly; this is followed by a *maintenance phase,* during which treatment intervals are slowly spread out and the drugs are given less frequently.

An important question is how long chemotherapy should be continued beyond the point at which complete remission has been achieved; that is, how long should the maintenance phase last or, for that matter, should maintenance therapy be used at all? In most human LSA protocols, after a 6-month induction phase, no benefit has been shown with continued maintenance therapy, therefore no further therapy is given until recurrence is observed. Recent evidence suggests that use of a DOX-containing, multiagent protocol (Table 181-4) for 6 months, followed by monthly re-evaluation, results in remission and survival times similar to those achieved with protocols involving a prolonged maintenance phase.[12,13]

The most effective and commonly used single agent chemotherapy protocol available for dogs with LSA is DOX.[11,48–50] DOX is administered at a dosage of 30 mg/m^2 given intravenously every 3 weeks for five treatments. Response is observed in 75% to 80% of cases, and median remission and survival durations of approximately 5 and 7 months, respectively, are reported. The advantages of this single agent protocol are that it is less time-consuming and expensive, and fewer hospital visits are required. Because only one drug is used, any side effects encountered are attributable to that drug.

If financial or other client concerns preclude the use of more aggressive systemic chemotherapy, prednisone therapy alone (2 mg/kg given orally daily) often results in short-lived remissions of approximately 1 to 2 months. In these cases, it is advisable to inform clients that if they should decide to pursue more aggressive therapy at a later date, dogs with prior prednisone therapy may be more likely to have drug-resistant disease and to experience shorter remission and survival durations with subsequent chemotherapy protocols. This is especially true after long-term prednisone use or in dogs that have experienced a recurrence while receiving prednisone.[51]

Modifications in the chemotherapy dose and/or frequency may be necessary under conditions of excess toxicity, as discussed in Chapters 178 and 179. When hypercalcemia is present, if the dog has substage A disease and continues to eat and drink, ancillary therapy for the hypercalcemia is usually unnecessary, because initiation of chemotherapy results in eucalcemia within a few days. If the animal is ill, azotemic, or showing signs attributable to hypercalcemia, therapy directed specifically at hypercalcemia (see Chapter 237) concurrent with the initiation of systemic chemotherapy is warranted.

736
737

Table • 181-4 University of Wisconsin–Madison Combination Chemotherapy Protocol for Dogs With Lymphoma

TREATMENT WEEK	DRUG, DOSAGE, AND ROUTE	TREATMENT WEEK	DRUG, DOSAGE, AND ROUTE
1	Vincristine: 0.5–0.7 mg/m^2 IV[a] L-asparaginase: 400 U/kg SC[b] Prednisone: 2 mg/kg PO[c]	11	Vincristine: 0.5–0.7 mg/m^2 IV
2	Cyclophosphamide: 250 mg/m^2 IV Prednisone: 1.5 mg/kg PO	13	Cyclophosphamide: 250 mg/m^2 IV
3	Vincristine: 0.5–0.7 mg/m^2 IV Prednisone: 1 mg/kg PO	15	Vincristine: 0.5–0.7 mg/m^2 IV
4	Doxorubicin: 30 mg/m^2 IV Prednisone: 0.5 mg/kg PO	17	Doxorubicin: 30 mg/m^2 IV
6	Vincristine: 0.5–0.7 mg/m^2 IV	19	Vincristine: 0.5–0.7 mg/m^2 IV
7	Cyclophosphamide: 250 mg/m^2 IV	21	Cyclophosphamide: 250 mg/m^2 IV
8	Vincristine: 0.5–0.7 mg/m^2 IV	23	Vincristine: 0.5–0.7 mg/m^2 IV
9*	Doxorubicin: 30 mg/m^2 IV	25†	Doxorubicin: 30 mg/m^2 IV

NOTE: A CBC should be performed before each chemotherapy treatment. If the neutrophil count is less than 2000 cells/μL, the clinician should wait 5 to 7 days and then repeat the CBC; the drug is administered if the neutrophil count has risen above the 2000 cells/μL cutoff.

* If the patient is in complete remission at week 9, treatment continues to week 11.

† If the patient is in complete remission at week 25, therapy is discontinued and the dog is rechecked monthly for recurrence.

181.1.6.2 Systemic Chemotherapy in Cats with Lymphoma

Several combination chemotherapy protocols for cats have been reported and reviewed previously.[17–19,52] It has become clear that the addition of DOX to COP-based protocols (*C,* cyclophosphamide; *O,* Oncovin [vincristine]; *P,* prednisone) is superior to COP alone in the cat.[17,52] However, in one European study, cats receiving COP experienced remission and survival durations comparable to cats treated with CHOP protocols in North America.[19] In contrast to dogs, DOX does not appear to be as effective single agent for

feline LSA.[53] In general, cats do not enjoy as high a response rate or as long remission and survival durations as dogs with LSA. Complete response rates vary between 50% and 75%, and overall median remission and survival durations are approximately 4 to 8 and 6 to 8 months, respectively.[17,19,54] However, a larger proportion of cats (30% to 40%) that achieve a complete response with combination chemotherapy enjoy more durable overall remission and survival times (i.e., 2 years) than that seen in dogs. Response rates and length of response vary according to the presence or absence of prognostic factors discussed under Prognosis. The modified CHOP-based protocol preferred by the authors for cats is represented in Table 181-5.

A recent preliminary report suggests that cats with low-grade gastrointestinal LSA may respond favorably and enjoy comparably long survival times using a protocol of oral chlorambucil (15 mg/m^2 given daily for 4 days, repeated every 3 weeks) and prednisone.[55]

Cats with large granular LSA or globule leukocyte tumors tend to respond more poorly to chemotherapy, although durable responses have been reported.[20]

181.1.6.3 Reinduction or Rescue Therapy

Ultimately, most dogs and cats with LSA successfully treated with chemotherapy relapse. This often represents a recrudescence of the tumor in a more drug-resistant form. Evidence suggests that recurrent LSA in dogs is more likely to express the gene encoding the P-glycoprotein transmembrane drug pump that is often associated with multiple drug resistance.[39–41] At the first recurrence of LSA, it is recommended that reinduction first be attempted by repeating of the induction protocol that was initially successful. In general, the likelihood of a response and the length of the response are half those seen with the initial therapy; however, a subset of animals will enjoy long-term reinductions. Recently it was shown that dogs that reached the observation phase using a no-maintenance protocol had a very high likelihood of a second response to the identical protocol.[13]

If reinduction fails or if the patient does not respond to the initial induction, so-called rescue agents or rescue protocols can be utilized. These drugs or drug combinations typically are not found in the standard CHOP protocol and are withheld for use in drug-resistant cases. A number of rescue protocols have been reported in the veterinary literature and have previously been reviewed.[46] The most common protocols used in dogs include single agent use or combination use of Actinomycin-D, mitoxantrone, lomustine (CCNU), DOX (if DOX was not part of the original induction protocol), DOX/dacarbazine combination, D-MAC (*D,* dexamethasone; *M,* melphalan; *A,* Actinomycin-D; *C,* cytosine arabinoside) and MOPP (*M,* methclorethamine; *O,* Oncovin; *P,* procarbazine; *P,* prednisone). Mitoxantrone, DOX, and MOPP have also been advocated in cats with resistant relapse. In general, overall rescue response rates of 25% to 50% are reported; however, these responses are usually not durable. Median response durations of 1.5 to 2 months are the norm. A small subset of animals will enjoy longer remission durations.

181.1.6.4 Therapy for Extranodal Lymphoma

If extranodal involvement is part of a more generalized or multicentric disease process, the systemic therapies previously discussed should be instituted. Conversely, if the extranodal site is solitary and not part of a multicentric presentation, local therapy may be performed without institution of systemic chemotherapy. In these latter cases, strict adherence to staging diagnostics, including bone marrow evaluation and

radiographic/ultrasonographic imaging of the thorax and abdomen, are warranted to ensure that the process is localized. If the disease is confined, local surgery and/or radiotherapy is often effective (Figure 181-5). Clients should be informed that systemic LSA is likely to occur months to years later, and a regular recheck schedule should be instituted. It is the authors' opinion that systemic therapy should be withheld until systemic disease has been documented. 738

Table • 181-5 University of Wisconsin–Madison Combination Chemotherapy Protocol for Cats With Lymphoma

TREATMENT WEEK	DRUG, DOSAGE, AND ROUTE	TREATMENT WEEK	DRUG, DOSAGE, AND ROUTE
1	Vincristine: 0.5–0.7 mg/m^2 IV L-asparaginase: 400 U/kg SC Prednisone: 2 mg/kg PO	11	Vincristine: 0.5–0.7 mg/m^2 IV
2	Cyclophosphamide: 200 mg/m^2 IV Prednisone: 2 mg/kg, PO	13†	Cyclophosphamide: 200 mg/m^2 IV
3	Vincristine: 0.5–0.7 mg/m^2 IV Prednisone: 1 mg/kg PO	15	Vincristine: 0.5–0.7 mg/m^2 IV
4	Doxorubicin: 25 mg/m^2 IV Prednisone: 1 mg/kg, PO*	17	Doxorubicin: 25 mg/m^2 IV
6	Vincristine: 0.5–0.7 mg/m^2 IV	19	Vincristine: 0.5–0.7 mg/m^2 IV
7†	Cyclophosphamide: 200 mg/m^2 IV	21†	Cyclophosphamide: 200 mg/m^2 IV
8	Vincristine: 0.5–0.7 mg/m^2 IV	23	Vincristine: 0.5–0.7 mg/m^2 IV
9‡	Doxorubicin: 25 mg/m^2 IV	25§	Doxorubicin: 25 mg/m^2 IV

NOTE: A CBC should be performed before each chemotherapy treatment. If the neutrophil count is less than 2000 cells/L, the clinician should wait 5 to 7 days and then repeat the CBC; the drug is administered if the neutrophil count has risen above the 2000 cell/μ L cutoff.

† If renal or CNS lymphoma is present, substitute cytosine arabinoside (600 mg/m^2 SC bid over 2 days) at these treatments.

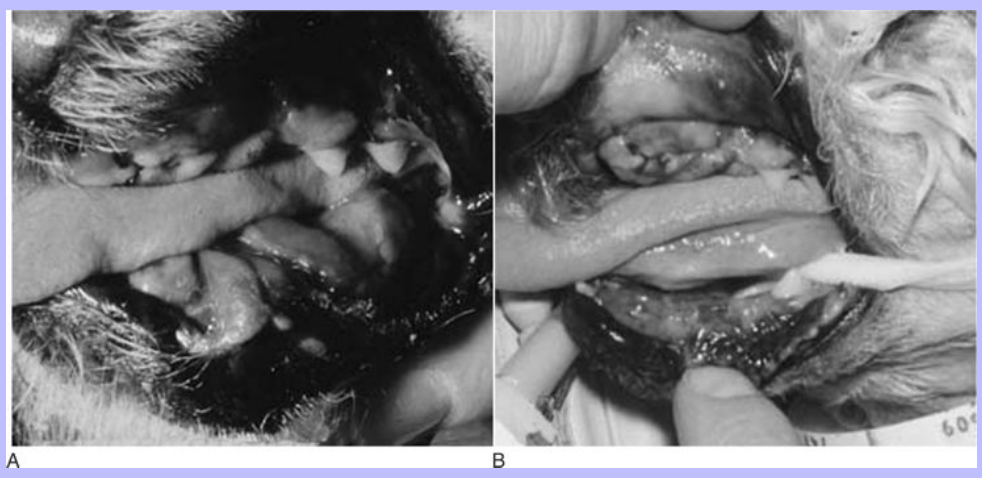
* Prednisone (1 mg/kg, PO) is continued every other day from this point on.

‡ If the patient is in complete remission at week 9, continue to week 11.

§ If the patient is in complete remission at week 25, therapy is discontinued and the cat is rechecked monthly for recurrence.

In cases in which CNS involvement is part of a more generalized process, penetration by chemotherapeutic drugs through the blood-brain barrier (BBB) may be a concern, and additional therapies are recommended. In standard CHOP protocols, only prednisone consistently penetrates the BBB. The addition of cytosine arabinoside, which achieves therapeutic CSF levels, to a CHOP-based protocol is recommended in such cases. Radiotherapy can also be effective, directed either to the entire neural axis (multifocal CNS lymphosarcoma) or to specific CNS locations (solitary central or spinal LSA). Cytoreductive surgery has been attempted in a small number of cases of extradural LSA in both cats and dogs, with mixed results.[44–46] 738 739

Figure 181-5 **A,** Solitary gingival lymphoma in a dog staged negative for systemic involvement. **B,** The same dog 6 months after external beam radiation therapy (48 Gy total dose). A complete response and long-term survival were achieved.



Cutaneous LSA in solitary sites has been effectively treated with local surgery or radiotherapy, but the likelihood of ultimate systemic involvement is high. Multiple cutaneous lesions are more commonly encountered (see Figure 181-2), and systemic therapy is necessary. In general, cutaneous LSA tends to be less responsive to chemotherapy than multicentric LSA, and clinical signs can wax and wane considerably over time. Responses have been reported with oral cis-retinoic acid therapy (Accutane®, 1 to 3 mg/kg given orally twice a day), Doxil® (a liposome encapsulated form of DOX), L-asparaginase, dacarbazine, lomustine, topical nitrogen mustard, and standard CHOP-based protocols.[57–60] Response rates are approximately 40% to 50%, and long-term survival is uncommon.

181.1.7 Prognosis

181.1.7.1 Prognostic Factors in Dogs

A list of factors known or suspected to affect remission rates and/or remission and survival durations in dogs with LSA is presented in Table 181-6. Age and breed do not affect the duration of remission or survival, and most studies fail to correlate the clinical stage to the prognosis except in dogs with marked stage V disease; that is, if bone marrow is heavily infiltrated, if overt leukemia is present, or if peripheral cytopenias exist secondary to myelophthisis. The two factors that most consistently correlate with the prognosis in dogs with LSA are the immunophenotype and the WHO substage.[9–14,16,29] Many reports have confirmed that dogs with CD3 immunoreactive tumors (i.e., T cell derived) have significantly shorter remission and survival durations (Figure 181-6). Similarly, dogs presenting with substage b disease (i.e., clinically ill) do poorly compared with dogs with substage a disease (Figure 181-7).

Other factors reported to correlate with the prognosis are less consistent; that is, they are not found to correlate in all studies, are preliminary reports, or contradictory reports exist in the literature. Some correlate after univariate analysis; however, when scrutinized by multivariate analysis (in which all factors are considered together), they are no longer significant. An example is the presence of hypercalcemia. In several reports, the presence of hypercalcemia is associated with a poor prognosis; however, if multivariate analysis is performed, hypercalcemia is no longer predictive, primarily because dogs with hypercalcemia are more likely to have T cell–derived LSA, which is a much stronger prognostic factor.

Table • 181-6 Factors Known or Suspected to Affect the Prognosis in Dogs With Lymphoma

FACTOR	STRENGTH OF ASSOCIATION	COMMENTS
World Health Organization (WHO) clinical stage	Weak	This factor is likely predictive of the outcome only in stage V disease with marked marrow involvement.[16]
WHO substage	Strong	Dogs with substage b disease have shorter remission and survival durations.[9,10,11,13,14]
Immunophenotype	Strong	Dogs with T-cell lymphoma have shorter remission and survival durations than dogs with B-cell tumors[9,14,16,19,29]
Hypercalcemia	Moderate	Poorer prognosis is not independent; rather, it is more likely due to T-cell association.[10,11]
Prolonged steroid pretreatment	Moderate	Most studies show previous steroid use shortens response durations.[9,10,29,113]
Sex	Weak	Some studies report that males have shorter remission and survival durations; other reports are contradictory.[9,35]
Proliferation rate Cranial mediastinal lymphadenomegaly	Weak Moderate to strong	Reports are contradictory.[25,29] Large compilation of cases shows association with shorter remission and survival durations; other reports arecontradictory.[16]
Histologic grade	Moderate	Low-grade tumors are less likely to respond to chemotherapy; however, patients may live longer despite this.[40,41]
P-glycoprotein expression	Moderate	This factor is associated with poor response rates and shorter remission and survival durations.

181.1.7.2 Prognostic Factors in Cats

Unlike in the dog, CD3 immunoreactivity has not been established as a negative prognostic factor in the cat.[17] This may reflect the wider variations in frequency of the different anatomic forms of LSA encountered in cats and the difficulty of distinguishing differences. Factors most strongly associated with a more positive prognosis in cats appear to be complete response to therapy (which unfortunately cannot be determined prior to treatment), negative FeLV status, early clinical stage, substage a disease, and the addition of DOX to the treatment protocol.[17,19,52,54,61] Early reports may contradict more recent studies, partly because FeLV associated LSA is declining, and early literature may not equate to more recent populations studied.[19] In

general, FeLV-negative cats that achieve a complete response on CHOP-based protocols have a high likelihood of long-term survival, with approximately 35% alive at 1.5 years after diagnosis. Cats with nasal LSA, overall, have the best prognosis, because local radiotherapy (or chemotherapy, if radiotherapy is not available) results in excellent control, with median survival times approaching 1.5 years.

181.1.7.3 The Future of Lymphoma Therapy

Based on the similarity of results achieved using the many and varied combination chemotherapy protocols, it is unlikely that currently available chemotherapeutics will significantly improve the outcome in dogs and cats with LSA. All combination protocols reported to date stop short of the same 10-to 12-month median survival "brick wall." Advances in remission and survival durations await the development of new agents or novel treatment modalities. Mechanisms of avoiding or abrogating multidrug resistance, enhancing tumor apoptosis (programmed cell death), utilization of chemotherapy/radiotherapy combinations, and novel immunomodulatory therapies (e.g., antibodies, vaccination strategies) are all active areas of investigation in both human and veterinary oncology. As practitioners who experience both the gratification that comes with high initial response rates and the frustration of equally high relapse rates, we eagerly await the advancement of these treatment modalities.

739
741

Figure 181-6 Kaplan-Meier survival duration estimates for a group of 55 dogs with lymphoma treated with an identical CHOP-based combination chemotherapy protocol at the University of Wisconsin. Dogs with CD3 immunoreactive (T-cell) lymphoma had significantly shorter survival durations.

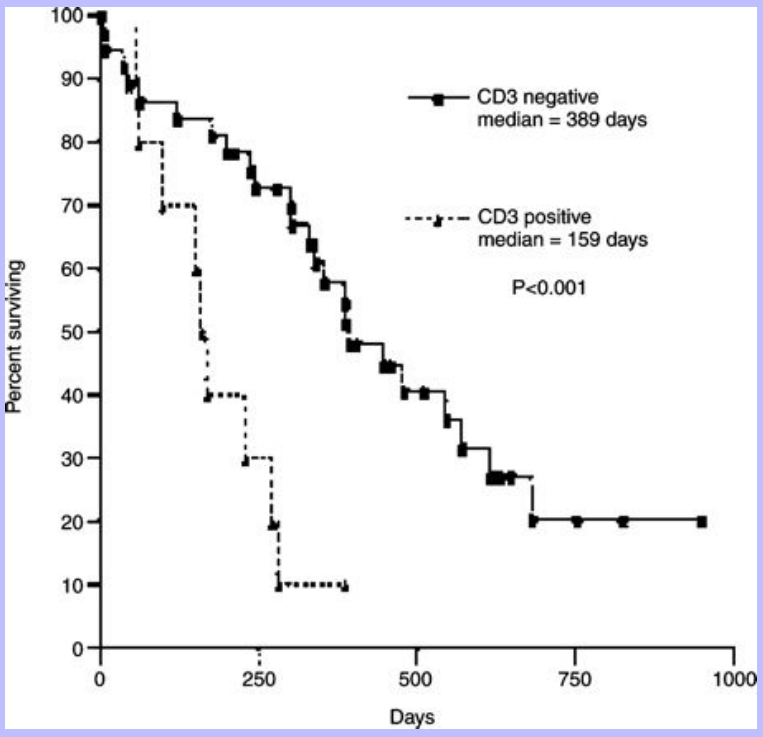


Figure 181-7 Kaplan-Meier survival duration estimates for a group of 55 dogs with lymphoma treated with an identical CHOP-based combination chemotherapy protocol at the University of Wisconsin. Dogs with substage b disease (i.e., those that were clinically ill) had significantly shorter survival durations.

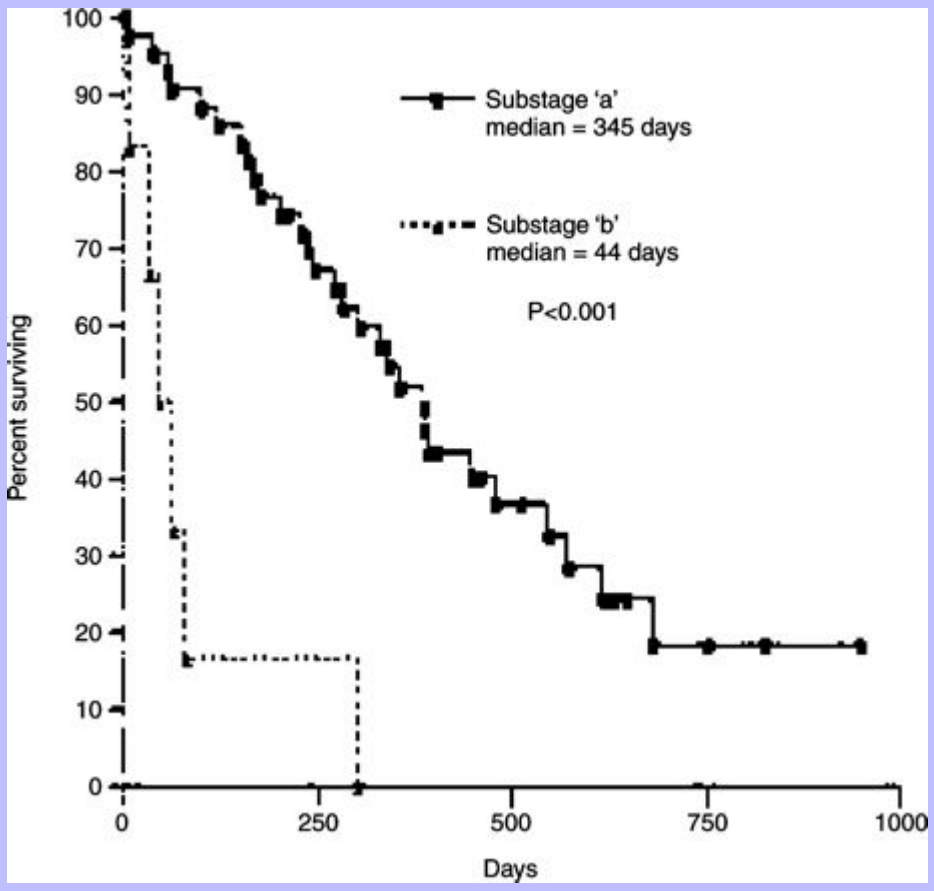


181.2 LYMPHOID LEUKEMIA

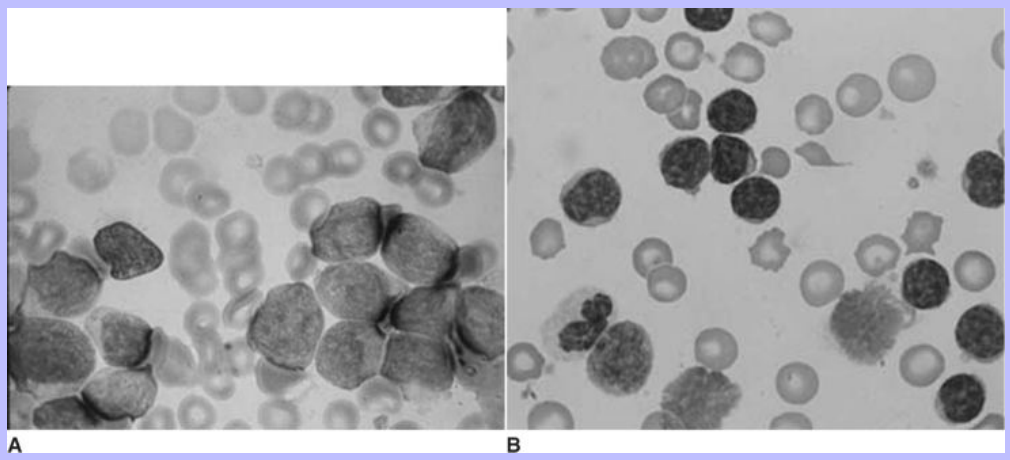
Leukemia is defined as a proliferation of neoplastic cells in the bone marrow. An important distinction is that by definition, the malignant cells may or may not be present in the peripheral blood circulation. Categorization of lymphoid leukemia into acute lymphoblastic leukemia (ALL) and chronic lymphocytic leukemia (CLL) is important from a diagnostic, prognostic, and therapeutic standpoint (Figure 181-8). Both forms are relatively rare in companion animals.[62–66]

181.2.1 Acute Lymphoblastic Leukemia

ALL is characterized by proliferations of morphologically immature lymphoblasts in the bone marrow or peripheral blood. ALL may be confused with multicentric LSA in dogs that also have advanced stage V disease (i.e., secondary bone marrow infiltration). However, the primary component of ALL is leukemia. The clinical course is rapid, progressive, and poorly responsive to therapy.[62,64]

No breed or sex predilection exists for dogs with ALL. Middle-aged to older dogs are typically affected. Cats with ALL are usually younger and are often FeLV antigenemic.[66] Presentations are nonspecific and commonly include lethargy, weight loss, intermittent pyrexia, hepatosplenomegaly, and nonspecific abdominal pain. Neurologic signs, both central and peripheral, have been reported. The majority of affected animals are anemic, and varying degrees of thrombocytopenia and leukopenia are commonly present.

Figure 181-8 **A,** Peripheral blood smear (Wright-Giemsa stain, ×1000) from a dog with acute lymphoblastic leukemia (ALL). Note the morphologically immature lymphoblasts characteristic of ALL. **B,** Peripheral blood smear (Wright-Giemsa stain, ×1000) of a dog with chronic lymphocytic leukemia (CLL). Note the morphologically mature lymphocytes characteristic of CLL. (Courtesy Dr. Karen Young, University of Wisconsin—Madison.)



The diagnosis is confirmed by documentation of marked lymphoblast proliferation in the bone marrow or peripheral blood. Bone marrow aspirate or core biopsy and a complete blood count are usually all that are required for diagnosis. Aspiration cytology of lymph node and involved organs and conformation of retroviral status in cats may be contributory. The presence of 30% or more lymphoblasts in the bone marrow is considered diagnostic. Approximately 10% of cases are classified as “aleukemic” leukemia because bone marrow infiltration is present but peripherally circulating lymphoblasts are absent. ALL may be further differentiated clinically from stage V multicentric LSA by its more rapid progression, lack of significant lymphadenopathy in approximately 50% of cases, poor chemoresponsiveness, and short survival times.

The prognosis is generally poor for dogs and cats with ALL.[62,64–66] Combination chemotherapy protocols designed to treat LSA result in remission in approximately 25% of cases, but remission durations are usually quite short, and survival times of more then a few months are rare. A short-term response to low-dose cytosine arabinoside (10 mg/m^2 given subcutaneously twice a day) has been reported in a cat.[67]

181.2.2 Chronic Lymphocytic Leukemia

CLL is characterized by the proliferation of phenotypically mature lymphocytes rather than lymphoblasts. Interestingly, recent immunophenotypic and clonotypic analysis has shown that the majority of CLL cases in dogs arise from CD8+ T cells, many of which show a large granular lymphocytic morphology.[68] CLL is reported primarily in older dogs and cats. The clinical presentation is nonspecific and may include lethargy, organomegaly, pyrexia, polyuria/polydipsia, hemorrhage (from thrombocytopenia), intermittent lameness, and collapse.[63] Most dogs present with mild to moderate lymphadenopathy, splenomegaly, and pale mucous membranes. However, asymptomatic lymphocytosis may be detected on routine geriatric or preanesthetic screening in some animals.

741

742

A normocytic, normochromic, nonregenerative anemia usually accompanies a marked mature peripheral lymphocytosis, which may range from 10,000 to 300,000/μL or more. Thrombocytopenia and neutropenia may be present as a result of myelophthisis. Although a minority of cases present with hyperglobulinemia, after immunoelectrophoresis, approximately half have evidence of a monoclonal gammopathy, often with Bence Jones proteinuria. No association with FeLV infection has been documented in the cat. Unlike ALL, CLL can have a protracted clinical course and is usually initially responsive to chemotherapy.[63] Treatment is not instituted unless significant clinical signs, organomegaly, or peripheral cytopenias (anemia, neutropenia, thrombocytopenia) are present that affect or threaten the animal's quality of life. Cases of CLL have been followed for many months without the necessity for therapy. If therapy is indicated, chlorambucil (*dogs:* 0.2 mg/kg given orally daily for 10 days, then 0.1 mg/kg/day; *cats:* 2 mg/cat given orally every other day) is combined with prednisone (2 mg/kg given orally daily). The dosage is adjusted based on the response. Approximately 75% of animals respond and enjoy a normal quality of life, with a median survival time of approximately 1 year. Although the prognosis is good in the short term, eventually CLL becomes resistant to therapy or progresses to ALL. When this happens, lymphoblasts replace mature lymphocytes as the abnormally proliferating population, and survival is short.

181.3 NONLYMPHOID LEUKEMIAS AND MYELOPROLIFERATIVE DISORDERS

Myeloproliferative disorders (MPDs) are defined as a group of nonlymphoid bone marrow cell disorders in which proliferation of one, several, or all of the marrow cell lines occurs. The disorders may represent preneoplastic or neoplastic conditions that may have a benign or malignant course. These are rare conditions in companion animals. With few exceptions (see Polycythemia Vera [Primary Erythrocytosis], p. 743), the veterinary literature on MPDs is sparse at best and is composed almost entirely of single case reports. Our experience with MPDs, therefore, is almost exclusively anecdotal, and specific characterizations and therapeutic recommendations are lacking.

Table • 181-7 Myeloproliferative Disorders Reported in Dogs and Cats

CLASSIFICATION	CELL LINEAGE	SELECTED REFERENCES
Acute Myeloproliferative Disorders		
Acute myelogenous leukemia (AML)	Myeloblasts	64–66
Acute myelomonocytic leukemia (AMML)	Myeloblasts/monoblasts	64–66, 69–71
Acute monocytic leukemia (AmoL)	Monoblasts	64–66, 72
Acute megakaryoblastic leukemia (AmkL)	Megakaryoblasts	73–79
Erythroleukemia	Erythroblasts	66, 80
Chronic Myeloproliferative Disorders		
Chronic myelogenous leukemia (CML)	Neutrophils, late precursors	82–84
Primary thrombocythemia	Platelets	84, 85
Basophilic leukemia	Basophils and precursors	86, 87
Eosinophilic leukemia	Eosinophils and precursors	88, 89
Polycythemia vera	Erythrocytes	84, 90–94

181.3.1 Classification

In general, MPDs are classified first on the basis of the derivation of the cell in question and second on the degree of cellular differentiation. If the proliferating cell population is mature or microscopically typical of a well-differentiated bone marrow cell line, the disorder is classified as chronic; if an immature or poorly differentiated cell line is present, the disease is classified as acute. Table 181-7 lists the MPDs reported in the veterinary literature. Because pluripotent bone marrow stem cells are involved, one MPD may evolve into another, and more often than not, more than one cell line is involved in the same disorder.

181.3.2 Clinical Presentation

Animals with a chronic MPD may have no clinical signs until organ involvement or bone marrow myelophthisis results in systemic disease. Clinical signs in dogs with late-stage chronic MPD or acute MPD are generally nonspecific and can include organomegaly, pallor, sepsis, and hemorrhage from thrombocytopenia. Most MPDs have been associated with FeLV infection in cats.

181.3.3 Diagnosis

The diagnosis of MPD is based on demonstration of the proliferating cell line in the absence of non-neoplastic diseases associated with bone marrow hyperplasia or hypoplasia. Differential diagnoses therefore include chronic inflammatory diseases (e.g., ehrlichiosis), multicentric LSA, estrogen toxicity, lead poisoning and, in the case of essential or primary thrombocytosis, iron deficiency. Because many of the acute MPDs are poorly differentiated and/or represent combinations of cell lineages, light microscopic morphology often is insufficient to determine the specific cellular derivation. Histochemistry, immunohistochemistry, and flow cytometric analysis are ultimately necessary in many instances for precise classification. Several private and academic laboratories perform these analyses. A complete listing of available tests is beyond the scope of the present chapter; these have been reviewed elsewhere.[95,96]

181.3.4 Therapy

The acute MPDs are generally poorly responsive to single agent or combination chemotherapy protocols, therefore their prognosis is grave. Several agents and combinations have been tried, including DOX, cytosine

arabinoside, 6-thioguanine, and CHOP-based protocols.[64–66,76] Response rates are low, and overall survival times are generally short. If chemotherapy is pursued, aggressive supportive therapy is usually necessary and may include whole blood or blood-component therapy to address cytopenias secondary to myelophthisis, antibiotic support, and aggressive fluid therapy.

Chronic MPDs carry a guarded prognosis; however, initial durable responses to therapy are more likely than with an acute MPD. Therapy is not required until clinical signs or significant peripheral cytopenia develops. Hydroxyurea has been used successfully in the treatment of several types of chronic MPD, particularly polycythemia vera (see below), essential thrombocythemia, basophilic leukemia, and chronic myelogenous leukemia (CML).[81,85–87,97,98] In dogs with CML, hydroxyurea is administered at an initial dosage of 20 to 25 mg/kg given orally twice daily. This dosage is continued until the leukocyte count drops to less than 20,000 cells/μL, at which time the dosage is reduced to 10 to 15 mg/kg daily or switched to 50 mg/kg given orally once every 2 to 3 weeks. A common side effect of hydroxyurea therapy in dogs is onychomadesis (sloughing of the claw or toenail). In dogs that respond to hydroxyurea therapy, survival times of many months have been reported. Ultimately, many of the chronic MPDs shift into a terminal phase or *blast crisis,* in which a fatal acute leukemic phase is observed.

181.3.5 Polycythemia Vera (Primary Erythrocytosis)

Polycythemia vera (PV) is defined as an abnormal proliferation of erythroid precursors in the bone marrow; this occurs independent of erythropoietin (EP), and the cells follow a normal, orderly pattern of maturation. The result is an abnormally elevated packed cell volume, erythroid count, and blood hemoglobin level. PV must be differentiated from so-called relative polycythemia or secondary polycythemia. Relative polycythemia is a result of hemoconcentration secondary to severe dehydration, body fluid shifts, or acute splenic contraction in dogs. It is readily corrected with fluid-based therapies. Secondary polycythemia is defined as EP-mediated erythrocytosis. Conditions associated with secondary polycythemia include right-to-left cardiac shunts, congestive heart failure, severe chronic pulmonary disease, some forms of renal disease, and neoplasms that secrete EP or EP-like substances.

Middle-aged dogs and cats are typically affected.[84,90–94] Clinical signs and physical findings associated with PV include hyperemic mucous membranes, injected scleral and retinal vessels, weakness, exercise intolerance, frank hemorrhage (epistaxis, hematuria, melena), neurologic signs (dementia, seizures, paralysis, ataxia), and occasional splenomegaly. Cardiac or renal compromise may also be present. The majority of signs reported occur secondary to hyperviscosity syndrome, discussed at length in the plasma cell tumor portion of this chapter.

The diagnosis is made by documentation of significant erythrocytosis (60% to 75% hematocrit) with normal to decreased serum EP levels and the absence of conditions associated with relative or secondary polycythemia. Thoracic and abdominal radiographs, abdominal ultrasound, arterial blood gas determinations, bone marrow aspirate testing, and serum EP levels should be procured to rule out differentials. Erythroid hyperplasia with relatively normal patterns of maturation is found on bone marrow cytology. Radioactive chromium determinations of red blood cell mass may contribute to the diagnosis.

Therapy for PV involves reduction of the red blood cell mass and suppression of erythroid production in the bone marrow. Reduction of the red blood cell mass can easily be achieved by phlebotomy (15 to 20 cc/kg body weight) and reinfusion of the patient's plasma after removal of the red blood cells.[91–93] Several techniques can be used to suppress erythrocyte production, including the use of radioactive phosphorous (^{32}P) or, more commonly available, chemotherapy.[84,97] The antineoplastic drug of choice is hydroxyurea, although alkylating

agents such as melphalan, cyclophosphamide, and busulfan have also been used, with mixed results. Hydroxyurea therapy is instituted at a dosage of 20 to 25 mg/kg given orally twice a day in dogs (10 to 15 mg/kg in cats). Once the hematocrit is below 60%, hydroxyurea is given every other day. Complete blood counts must be carefully monitored for potential myelosuppression of other cell lineages. Most cases of PV respond to therapy, and survival times of a year or longer are the norm. Progression to leukemia is reported in some humans with the disease.

181.4 PLASMA CELL NEOPLASMS

Plasma cell neoplasms are defined as neoplastic proliferations of cells of the B-lymphocyte plasma cell lineage. This population is believed in most instances to be monoclonal (i.e., derived from a single cell), because it typically produces homogenous immunoglobulin. Plasma cell neoplasms include multiple myeloma, IgM (Waldenstrom's) macroglobulinemia, and solitary plasmacytoma (including solitary osseous plasmacytoma and extramedullary plasmacytoma). Multiple myeloma is the most important plasma cell neoplasm based on incidence and severity.

181.4.1 Multiple Myeloma

Multiple myeloma (MM) is responsible for approximately 8% of all canine hematopoietic tumors.[99] The true incidence of MM in the cat is unknown; however, it is much less common than in the dog.[100] In MM, malignant plasma cells produce an overabundance of a single type, or component, of immunoglobulin, which is referred to as the M-component. Rarely, biclonal immunoglobulin production has been reported.[101] The M-component may represent any class of immunoglobulin or only a portion of the molecule, such as the light-chain (Bence Jones protein) or heavy chain (heavy chain disease) of the molecule.

181.4.2 Etiology

The etiology of MM is for the most part unknown. Genetic predispositions, viral infections, chronic immune stimulation, and exposure to carcinogens have all been suggested as contributing factors.[102–104] MM has not been associated with either FeLV or FIV infection.

181.4.3 Pathophysiology

A wide array of pathologic abnormalities and related clinical syndromes can occur as a result of tumor infiltration of various organ systems, the presence of high levels of circulating M-component, or a combination thereof.

Hyperviscosity syndrome (HVS) represents one or a constellation of clinicopathologic abnormalities resulting from greatly increased serum viscosity. The magnitude of HVS is related to the type, size, shape, and concentration of the M-component in the blood. It is more common with IgM macroglobulinemias because of their high molecular weight; however, IgA-and IgG-associated HVS can occur, albeit less frequently.[99,105,106] High serum viscosity occurs in approximately 20% of dogs with MM and can result in bleeding diathesis, neurologic signs (e.g., dementia, depression, seizure activity, coma), ophthalmic abnormalities (e.g., dilated and tortuous retinal vessels, retinal hemorrhage, retinal detachment), and increased cardiac workload with the potential for subsequent development of cardiomyopathy or congestive failure.[99,105–110] These consequences are thought to be a result of sludging of blood in small vessels, ineffective delivery of oxygen and nutrients, and

coagulation abnormalities. HVS is less common in cats but has been reported in association with IgG-, IgA-, and IgM-secreting tumors.[106,111–114]

Renal disease is present in 30% to 50% of dogs with MM.[99] This can occur as a result of Bence Jones (light chain) proteinuria, tumor infiltration into renal tissue, hypercalcemia, amyloidosis, diminished perfusion secondary to hyperviscosity syndrome, dehydration, or ascending urinary tract infection. Bence Jones proteinuria (BJP) occurs in approximately 25% to 40% of dogs with MM; the true incidence of BJP in cats is not well established.

Hypercalcemia occurs in 15% to 20% of dogs with MM and is thought to result primarily from the production of osteoclast-activating factor or other cytokines (e.g., interleukin-6) by neoplastic cells.[99,106] In two dogs with MM and hypercalcemia, serum elevations in circulating N-terminal parathyroid hormone–related protein were noted, although its relative contribution to hypercalcemia is unknown.[115] Hypercalcemia may be exacerbated by associated renal disease. Hypercalcemia is rare in cats with MM.[116,117]

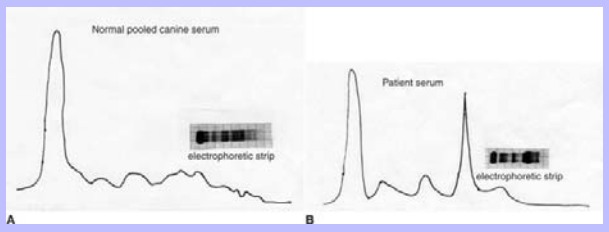
Susceptibility to infection and immunodeficiency are often the ultimate causes of death in animals with MM. Normal immunoglobulin levels are usually severely depressed, and leukopenias may be present secondary to marrow infiltration (myelophthisis).

Variable cytopenias may be observed in association with MM. A normocytic, normochromic, nonregenerative anemia is encountered in approximately two thirds of dogs.[99,106] This can result from myelophthisis, blood loss from coagulation disorders, anemia of chronic disease, or increased erythrocyte destruction secondary to high serum viscosity. Similar factors lead to thrombocytopenia and leukopenia in 25% to 30% of affected dogs.

Bleeding diathesis can result from one or a combination of events. M-components may interfere with coagulation in a number of ways, including inhibition of platelet aggregation and the release of platelet factor-3, adsorption of minor clotting proteins, generation of abnormal fibrin polymerization, production of heparin-like anticoagulants, and a functional decrease in calcium.[118]

Cardiac disease, if present, is usually a result of excessive cardiac workload and myocardial hypoxia secondary to hyperviscosity. Myocardial infiltration with amyloid and anemia may be complicating factors.

Figure 181-9 **A,** Serum protein electrophoresis from pooled normal dogs. Stained cellulose acetate electrophoretic strip with accompanying densitogram. **B,** Serum protein electrophoresis from a dog with multiple myeloma. Note the large M component spike (representing an IgA monoclonal gammopathy) in the gamma region.



181.4.4 Clinical Presentation and Signs

MM occurs in aged dogs and cats, and no breed or sex predilection has been consistently reported. Clinical signs are variable due to the wide range of pathologic effects possible and may be present up to one year prior to diagnosis.[99] The most common clinical signs in decreasing order of frequency are lethargy and weakness, lameness as a result of bone destruction, hemorrhage, polyuria/polydipsia, and neurologic deficits. Bleeding diathesis is usually represented by epistaxis and gingival bleeding. Central nervous system signs may include dementia, seizure activity, and deficiencies in midbrain or brain stem localizing reflexes secondary to HVS or extreme hypercalcemia. Signs reflective of transverse myelopathies secondary to vertebral column infiltration, pathologic fracture, or extradural mass compression can also occur.

In the cat, anorexia and weight loss are the most common clinical signs.[116,119,120] A history of chronic respiratory infections may be present. Skeletal lesions are uncommon in cats, but hepatosplenomegaly is more commonly seen due to organ infiltration.[116] Epistaxis, pleural and peritoneal hemorrhagic effusions, retinal hemorrhage, and central neurologic signs have been reported.[106,111–114,120] Polydipsia and polyuria can occur secondary to renal disease, and dehydration may develop. Hindlimb paresis secondary to osteolysis of lumbar vertebral bodies has been reported in a cat.[121]

181.4.5 Diagnosis

The diagnosis of multiple myeloma usually follows demonstration of bone marrow plasmacytosis and serum or urine myeloma proteins (M-component), as well as detection of osteolytic bone lesions (primarily in the dog). In the absence of osteolytic bone lesions, a diagnosis can be made if marrow plasmacytosis is associated with a progressive increase in the M-component.

All animals suspected of plasma cell tumors should receive a CBC, platelet count, serum biochemistry profile, and urinalysis. Particular attention is paid to renal function and serum calcium levels. Serum electrophoresis and immunoelectrophoresis are performed to detect a monoclonal spike (Figure 181-9) and to categorize the isotype of immunoglobulin involved. In the dog, the M-component is usually of the IgG or IgA class in nearly equal incidence.[99,106] If IgM constitutes the M-component, the term *macroglobulinemia* (i.e., Waldenstrom's macroglobulinemia) is used. Biclonal gammopathy has also been reported.[101,122] In the cat, MM is usually associated with IgG elevations; only a few cases of IgA or IgM gammopathies have been reported.[106,111–114,120,123] Occasionally, cryoglobulinemia has been reported in dogs and cats with MM.[106,124–126] Cryoglobulins are paraproteins that are insoluble at temperatures below 37° C and that require blood collection and clotting to be performed at 37° C before serum separation. If Bence Jones proteinuria is suspected, heat precipitation and electrophoresis of urine are necessary, because commercial urine dipstick methods are not capable of this determination. “Nonsecretory” varieties of multiple myeloma have been reported rarely in dogs.[127,128]

744 745

Definitive diagnosis usually requires a bone marrow aspirate or core biopsy. Normal marrow contains less than 5% plasma cells, whereas myelomatous marrow often greatly exceeds this level. Malignant plasma cells can have a varied microscopic appearance, ranging from that of normal plasma cells to early stages of differentiation.

Skeletal survey radiographs are recommended to determine the presence and extent of osteolytic lesions, which may have diagnostic, prognostic, and therapeutic implications. Rarely, biopsy of osteolytic lesions (i.e., Jamshidi core biopsy) is necessary for diagnosis. Bone lesions may be isolated, discrete lesions (including pathologic fractures) or diffuse osteopenias (Figure 181-10). Approximately 25% to 30% of dogs with MM have evidence of bony lysis or diffuse osteoporosis.[99,106] Bones engaged in active hematopoiesis are more commonly affected (e.g., vertebrae, ribs, pelvis, skull, and proximal long bones). Skeletal lesions are rare in cats with MM and in dogs with IgM (Waldenstrom's) macroglobulinemia.[106,119,120] In macroglobulinemia, malignant cells often infiltrate the spleen, liver, and lymphoid tissue rather than bone.[124,129]

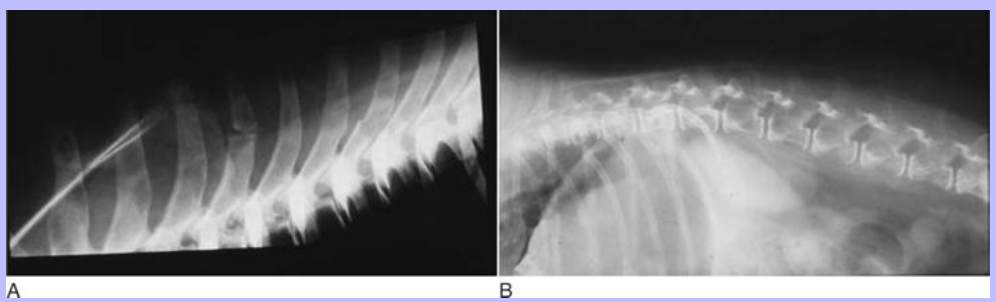
If clinical evidence of hemorrhage is present, coagulation assessment (e.g., platelet count, prothrombin time [PT], and partial thromboplastin time [PTT]) and serum viscosity measurements should be undertaken. Nearly half of these patients have abnormal PT and PTT values.

All animals should undergo a careful funduscopic examination; abnormalities may include retinal hemorrhage, venous dilatation with sacculation and tortuosity, retinal detachment, and blindness.

181.4.6 Differential Diagnosis

Disease syndromes other than MM can be associated with monoclonal gammopathies and should be considered in any list of differential diagnoses. These disorders include other lymphoid tumors (LSA, CLL, and ALL), chronic infections (e.g., ehrlichiosis, leishmaniasis, feline infectious peritonitis [FIP]), and monoclonal gammopathy of unknown significance (MGUS). MGUS (i.e., benign, essential, or idiopathic monoclonal gammopathy) is a benign monoclonal gammopathy that is not associated with osteolysis, bone marrow infiltration, or Bence Jones proteinuria.[130,131]

Figure 181-10 **A,** Lateral thoracic radiographs of a dog showing multiple expansile, lytic lesions in the axial skeleton, most apparent in the spinous processes of the vertebrae, as can be seen with multiple myeloma. **B,** Lateral vertebral radiographs of a dog with multiple myeloma. Note the overall decreased opacity of the lumbar vertebrae secondary to diffuse marrow involvement with tumor, which causes a loss of bone trabeculae and thinning of the cortices. (Courtesy Dr. Lisa Forrest, University of Wisconsin—Madison).



181.4.7 Treatment

181.4.7.1 Initial Therapy of Multiple Myeloma

Therapy should be directed at both the tumor cell mass and its secondary systemic effects. Chemotherapy is highly effective at reducing the myeloma cell burden, relieving bone pain, initiating skeletal healing, and reducing levels of serum immunoglobulins.[99,106] It significantly extends both the quality and length of most patients' lives. Complete elimination of neoplastic myeloma cells is rarely achieved, however, and although MM remains a gratifying disease to treat, eventual relapse is to be expected.

Melphalan, an alkylating agent, in combination with prednisone, is the treatment of choice. In the dog, the initial starting dose for melphalan is 0.1 mg/kg given orally once daily for 10 days; it is then reduced to 0.05 mg/kg given once daily continuously. Prednisone is initiated at a dosage of 0.5 mg/kg given orally once daily for 10 days, then reduced to 0.5 mg/kg every other day. Therapy continues until clinical relapse occurs or myelosuppression necessitates a dose reduction. The most clinically significant toxicity of melphalan is myelosuppression, particularly thrombocytopenia. Complete blood counts, including numeric platelet counts, should be performed biweekly for 2 months after initiation of therapy and monthly thereafter. If significant myelosuppression occurs, reduction of the dosage or the treatment frequency may be necessary. An alternative pulse dosing regimen for melphalan (7 mg/m^2 given orally daily for 5 consecutive days every 3 weeks) has been used successfully at the University of Wisconsin in a small number of cases in which myelosuppression limited more conventional continuous low-dose therapy. Melphalan and prednisone therapy can also be used in cats with multiple myeloma, although the results are generally less rewarding.

Cyclophosphamide can be used as an alternate alkylating agent, sometimes in combination with melphalan; however, there is no evidence to suggest that it is superior. In the authors' practice, cyclophosphamide is limited to cases presenting with severe hypercalcemia or widespread systemic involvement, in which a faster acting alkylating agent may more quickly alleviate the systemic effects of the disease. Cyclophosphamide is administered at a dosage of 200 mg/m^2 given intravenously once at the same time oral melphalan therapy is started. Chlorambucil, another alkylating agent, has been used successfully for the treatment of IgM macroglobulinemia in dogs at an initial dosage of 0.2 mg/kg given orally once daily.[106]

745 746

181.4.7.2 Evaluation of Response to Therapy

Response is based on improvement in clinical signs, clinicopathologic parameters, and radiographic improvement of skeletal lesions. Subjective improvement in bone pain, lameness, lethargy, and anorexia should be evident within 3 to 4 weeks. Objective laboratory improvement, including a reduction in serum immunoglobulin levels or Bence Jones proteinuria, is usually noted within 3 to 6 weeks. Radiographic improvement in osteolytic bone lesions may take months, and resolution may only be partial.

As previously discussed, complete resolution of multiple myeloma rarely occurs, and a good response is defined as a reduction in measured M-component (i.e., immunoglobulins or Bence Jones proteins) to at least 50% of pretreatment values.[106] For routine follow-up, quantitation of serum immunoglobulins via radial immunodiffusion or measurement of urine Bence Jones proteins is performed monthly until a good response is noted and then every 2 to 3 months. Repeat bone marrow aspiration is performed if warranted.

181.4.7.3 Therapy Directed at Complications of Multiple Myeloma

Long-term control of complications, including hypercalcemia, hyperviscosity syndrome, bleeding diathesis, renal disease, immunosuppression, and pathologic skeletal fractures, depends on control of the tumor mass. However, therapy directed more specifically at these complications may be indicated in the short term.

If hypercalcemia is marked and significant clinical signs exist, standard therapies are indicated (see Chapter 237). Moderate hypercalcemia typically resolves within 2 to 3 days of initiation of melphalan/prednisone chemotherapy.

Hyperviscosity syndrome is best treated in the short term by plasmapheresis. Whole blood is collected from the patient and centrifuged to separate plasma from packed cells. Packed red cells are resuspended in normal saline and reinfused into the patient. Bleeding diathesis usually resolves along with HVS; however, platelet-rich plasma transfusions may be necessary with thrombocytopenia.

Renal impairment may necessitate aggressive fluid therapy. Careful attention to secondary urinary tract infections and appropriate antimicrobial therapy are indicated. Patients with MM can be thought of as "immunologic cripples," and prophylactic antibiotic therapy in dogs with multiple myeloma has been advocated by some.[106] In humans, however, prophylactic antibiotic use is not superior to diligent monitoring and aggressive antimicrobial management when indicated.[132] Cidal antimicrobials with low potential for nephrotoxicity are preferred.

Pathologic fractures of weight-bearing long bones and vertebrae, resulting in spinal cord compression, may require immediate intervention in conjunction with systemic chemotherapy. Orthopedic stabilization of fractures should be undertaken and may be followed with external beam radiotherapy. Recently, inhibition of osteoclast activity by bisphosphonate drugs has been shown to reduce the incidence and severity of skeletal complications of MM in humans.[133] This class of drugs may hold promise for use in dogs and cats in the future.

181.4.7.4 Rescue Therapy

At the time of relapse or in cases initially resistant to melphalan, rescue therapy may be attempted. The authors have had success with a combination of DOX (30 mg/m^2 given intravenously every 21 days), vincristine (0.7 mg/m^2 given intravenously on days 8 and 15 of the cycle), and prednisone (1 mg/kg given orally daily) administered in 21-day cycles. Although most dogs initially respond to a rescue protocol, the duration of response tends to be short, lasting only a few months. High-dose cyclophosphamide (300 mg/m^2 given intravenously every 7 days) has also been used as a rescue agent, with limited success. A durable rescue with liposome-encapsulated DOX has been reported in a dog with MM.[134] In humans, the antiangiogenic and anticytokine drug thalidomide is an active agent in chemotherapy-refractory MM.[135] To the authors' knowledge, thalidomide has not been evaluated in veterinary MM patients.

181.4.8 Prognosis

The prognosis for dogs with MM is good for initial control of the tumor and a return to good quality of life. In a group of 60 dogs with MM, 43% achieved complete remission (i.e., serum immunoglobulins normalized) and

49% achieved partial remission (i.e., immunoglobulins less than 50% of pretreatment values); only 8% did not respond to melphalan and prednisone chemotherapy.[99] Long-term survival is the norm, with a median of 540 days reported. Hypercalcemia, Bence Jones proteinuria, and extensive bony lysis are known negative prognostic factors in the dog. The long-term prognosis for dogs is poor, because recurrence is expected. Eventually, the tumor no longer responds to available chemotherapeutics, and death follows from renal failure, sepsis, or euthanasia for intractable bone or spinal pain.

The prognosis for MM in the cat is not as favorable as in the dog.[112,116,119,120] Although most cats transiently respond to melphalan/prednisone or cyclophosphamide-based protocols, responses are not durable, and most patients succumb within 2 to 3 months. One long-term feline survivor has been reported.[117]

In nine dogs with IgM macroglobulinemia, response to chlorambucil occurred in the majority, and a median survival time of 11 months was reported.[106]

181.5 SOLITARY PLASMACYTOMA

Solitary collections of monoclonal plasmacytic tumors can originate in bone or soft tissues and are referred to as *solitary osseous plasmacytoma (SOP)* and *extramedullary plasmacytoma (EMP),* respectively. The majority of SOPs eventually progress to systemic MM.[128,136] Cutaneous EMP, including oral cavity EMP, is typically a benign disorder in dogs.[137] Conversely, the natural behavior of noncutaneous EMP appears to be much more aggressive. Gastrointestinal EMPs have been reported to involve the esophagus, stomach, and small and large intestine.[138–143] Metastasis to associated lymph nodes is common in these cases, although bone marrow involvement and monoclonal gammopathies are less commonly encountered. One report exists of subcutaneous EMP in a cat with IgG gammopathy; the EMP progressed to lymph node disease and distant metastasis.[144]

181.5.1 Clinical Signs

Clinical signs associated with solitary plasmacytomas relate to the location of involvement; in rare cases with high levels of M-component, HVS may occur. SOP usually is associated with pain and lameness if the appendicular skeleton is affected or with neurologic signs if vertebral bodies are involved. Cutaneous EMP usually has a benign course with no related clinical signs. Gastrointestinal EMP, however, typically presents with relatively nonspecific signs that may suggest alimentary involvement. One case of ataxia and seizure activity in a dog with EMP secondary to tumor-associated hypoglycemia has been reported.[145]

746

747

181.5.2 Diagnosis

The diagnosis of SOP and EMP requires tissue biopsy. It is important to thoroughly stage such cases of SOP and noncutaneous EMP with bone marrow aspirate, serum electrophoresis, and skeletal survey radiographs to ensure that disease is confined to a local site prior to initiation of therapy. In the case of poorly differentiated solitary plasmacytic tumors, immunohistochemical studies, directed at detecting immunoglobulin light and heavy chains and thioflavin-T, may be helpful in confirming a diagnosis.

181.5.3 Therapy

Animals with solitary plasma cell tumors may be treated with local therapy in the absence of systemic chemotherapy, provided thorough clinical staging does not reveal systemic involvement. Effective local control has been achieved with surgical excision or external beam radiotherapy, alone or in combination. Most dogs with noncutaneous SOP and EMP eventually develop systemic myeloma, and there exists controversy among veterinary oncologists as to whether systemic chemotherapy should be initiated at the time of local therapy. Systemic dissemination may not occur for many months to years beyond diagnosis in humans, and studies in humans reveal no benefit from initiation of systemic chemotherapy prior to the documentation of subsequent systemic involvement.[132]

Long-term follow-up of patients with solitary plasmacytoma is indicated to detect both recurrence of disease and systemic spread.

181.5.4 Prognosis

Dogs with cutaneous plasmacytomas are usually cured by means of surgical excision. Dogs with SOP or EMP of the alimentary tract treated by surgical excision (in combination with systemic chemotherapy once systemic disease is documented) enjoy long-term survival in the majority of cases.

182 CHAPTER • 182 Tumors of the Skin

Kenneth M. Rassnick

The skin is the most common site of occurrence for neoplasms in the dog and the second most common site in the cat. Subcutaneous and cutaneous tumors together account for at least one third of all canine tumors. Approximately 20% to 30% are histologically malignant.[1] Mast cell tumors, perianal adenomas, lipomas, histiocytomas, sebaceous gland adenomas, and papillomas are the most common histologic types of canine tumors.[1–4] Skin and subcutaneous tissues account for approximately one fourth of all tumors in the cat, and 50% to 65% are histologically malignant.[1,2,5] The histologic appearance of malignancy does not necessarily correlate with the tendency to metastasize. The most common skin tumors found in cats include basal cell tumors, mast cell tumors, squamous cell carcinoma, and fibrosarcoma.[2,5,6]

Tumors of the skin and subcutis can be broadly classified histologically according to their tissue of origin: epithelial, mesenchymal, round cell, or melanocytic (Box 182-1). Tumors can be further classified according to individual cell of origin as long as sufficient differentiation is present. This chapter focuses primarily on tumors of epithelial origin, melanocytic tumors, and some of the round cell tumors.

182.1 GENERAL APPROACH TO SKIN TUMORS

182.1.1 History and Physical Examination

Because lesions and masses involving the skin are easily seen, they are common reasons for owners to seek veterinary care. General history taking should include duration and rate of tumor growth, change in appearance over time, response to previous treatments, and related medical problems. All tumors should be accurately reported in the medical record. Topographic maps are helpful in making this documentation a permanent part of the record. Three-dimensional caliper measurements and the actual anatomic locations of masses should be recorded. The record should also include gross appearance (color, alopecia, ulceration), consistency (firm, soft), borders (circumscribed, infiltrative), and attachments to underlying tissues (fixed, movable). In addition to a complete physical examination of the animal, lymph nodes draining a skin mass should always be thoroughly evaluated.

182.1.2 Diagnostics

The key to the appropriate management of skin tumors is a specific diagnosis. In many circumstances, diagnosis and characterization of a skin mass should be done before a definitive surgical excision. Knowledge of the tumor type allows the clinician to plan an appropriate surgical approach, make decisions about the need for adjuvant radiation therapy or chemotherapy, and discuss realistic outcomes of therapy and prognosis with clients. Figure 183-2 in Chapter 183 shows an approach to the diagnosis of superficial masses based on initial fine needle aspiration cytology and tissue biopsy.

Routine hematologic and biochemical analyses are rarely helpful in the diagnosis of cutaneous masses; however, some skin tumors may be associated with hematologic or paraneoplastic complications (see Chapter 189). “Screening” blood tests are recommended before a definitive procedure is planned.

Radiographs of the thorax are required in the clinical staging of malignant skin tumors, and ultrasound evaluation of abdominal organs may be useful in the assessment of potential sites of metastases for some tumors. For tumors that deeply attach to underlying tissues, imaging modalities such as radiographs, computed tomography (CT), or magnetic resonance imaging (MRI) may be helpful for delineating tumor borders prior to surgical excision. 748

182.1.2.1 Box • 182-1 Common Skin and Subcutaneous Tumors

182.1.2.1.1 Epithelial Tumors

Papilloma

Intracutaneous cornifying epithelioma

Squamous cell carcinoma

Basal cell tumors

Trichoepithelioma

Pilomatricoma

Trichoblastoma

Sebaceous gland tumors

Hepatoid gland tumors (perianal gland tumors)

Sweat gland tumors (apocrine gland tumors)

Ceruminous gland tumors

Anal sac apocrine gland tumors

182.1.2.1.2 Mesenchymal Tumors

Soft tissue sarcomas (see Chapter 183)

182.1.2.1.3 Round Cell Tumors

Plasmacytoma

Mast cell tumor (see Chapter 186)

Lymphoma (see Chapter 181)

Histiocytoma (see Chapter 187)

Transmissible venereal tumor (see Chapter 188)

182.1.2.1.4 Melanocytic Tumors

Melanoma

Enlarged lymph nodes should always be evaluated cytologically or histologically. For some tumors (e.g., mast cell tumors), metastases may be present in lymph nodes that are palpably normal, therefore lymph node evaluation should be a routine part of the evaluation of an animal with a cutaneous mass.

182.1.2.2 Fine Needle Aspiration

Fine needle aspiration is easy and quick and often provides information about the neoplastic cell type. Fine needle aspiration cytology is most useful in the diagnosis of round cell tumors (e.g., mast cell tumors, cutaneous lymphoma) and for identifying benign skin tumors or papules, nodules, and masses that are non-neoplastic. When cytology is nondiagnostic, a biopsy should be performed. Likewise, when a cytologic diagnosis of neoplasia is obtained, a biopsy should always be done to confirm the diagnosis and assess important prognostic information, such as the degree of differentiation or the tumor grade, a description of vessel invasion, and an evaluation of tissue margins if an excisional biopsy is performed.

182.1.2.3 Biopsy

A number of biopsy techniques can be used, depending on the size and anatomic location of the mass. Incisional, needle core, or punch biopsies are indicated for large, infiltrative masses or for tumors in a difficult area for reconstruction (e.g., extremities, perineal or periocular regions). For superficial exophytic lesions, shave biopsies done with a scalpel blade may be adequate. For small, freely movable dermal masses, excisional biopsy can be both diagnostic and therapeutic. Even when the diagnosis is known prior to the excisional biopsy, the histopathology of the final specimen should also be determined because it may provide information useful for treatment planning.

When performing nonexcisional biopsies, clinicians should always carefully examine the region to be sampled. The biopsy site should be in an area that can easily be included in the definitive resection or, if indicated, radiation field. As a general rule, all biopsy incisions on extremities should be longitudinal along the axis of the limb. Injection of local anesthetics into cutaneous and subcutaneous tumors should be avoided. Tumor tissue is poorly innervated, and the mass itself does not require anesthesia. Local injections cause tissue distortion and make margin evaluation difficult. The biopsy should be taken deep enough to avoid superficial necrotic tissue and surrounding areas of inflammation. The biopsy procedure should never disrupt tissue planes. A biopsy that opens new and previously uninvolved tissue planes generally necessitates a wider surgical resection or radiation field to control local disease. Drain placement should be avoided, because it allows fluid that has been contaminated with neoplastic cells to contact all tissues through which the drain is placed. Similarly, formation of seromas or fluid pockets may allow tumor cells to invade previously uninvolved tissue planes.

An ideal histologic specimen should include the junction of the tumor with adjacent normal tissue. This allows the pathologist to assess the degree of invasiveness of the tumor. Sample size and consistency are important for obtaining accurate pathologic diagnoses. Most tumors are not homogenous, containing areas of inflammation, necrosis, and reactive tissue, and small samples may not be representative of the entire lesion. Samples smaller than 1 × 1 mm are usually inadequate. Needle core samples 1 mm wide and 5 mm long can be adequate. Samples that fall apart in formalin are often blood, mucus, or necrotic material and are not

sufficient for a diagnosis. Large biopsy samples or multiple biopsy specimens from different areas of the tumor (collected through the same incision) can improve chances for an accurate diagnosis.

Cautery and radiofrequency surgical instruments should not be used during the biopsy procedure because they alter tissue and cellular morphology, which may complicate interpretation. Cautery for hemostasis may be used once the sample has been removed.

Finally, applying India ink or other marking dyes to the cut surfaces of excised tumors prior to fixation in formalin is an effective way to ensure that the pathologist can distinguish surgical margins from preparation artifacts.

182.2 EPITHELIAL TUMORS

182.2.1 Papilloma

Cutaneous papillomas are benign proliferations of the epidermis and are common in the dog but relatively rare in cats. Grossly, they are whitish or gray, pedunculated or cauliflower-like masses and are often referred to as *warts* or *verrucae*. Both viral and nonviral forms exist. The papillomaviruses are species-specific deoxyribonucleic acid (DNA) viruses. They are fairly stable in the environment and can survive for longer than 2 months at 4° to 8° C and for 6 hours at 37° C.[7] Papillomaviruses can be transmitted by direct and indirect (e.g., fomite) contact. In general, infection occurs in damaged skin, and incubation times vary from 1 to 2 months.[7]

Cutaneous papillomas occur in older dogs, and single or multiple lesions may be seen. They most commonly occur on the head, eyelids, and feet and are not associated with papillomavirus. *Canine oral papillomatosis* is a contagious disease of viral origin that often affects young or immunocompromised dogs.[8] Multiple lesions occur in the mouth, pharynx, face, and skin. *Cutaneous inverted papillomas,* cup-shaped lesions seen in young dogs, are also caused by infection with a papillomavirus. They occur on the ventral abdomen and groin.[9] Rare cases of multiple, pigmented plaques, or *papular papillomas,* have been reported in dogs.[10]

748

749

In cats, most solitary cutaneous papillomas are not caused by papillomavirus. In contrast, papillomas that occur on the ventral tongue in cats are generally viral in origin, as are multiple cutaneous papillomas. These viral papillomas may be precursors to feline multicentric squamous cell carcinoma, or Bowen's disease (see Feline Squamous Cell Carcinoma, below).[11]

Surgical excision of solitary cutaneous papillomas is curative. Canine oral papillomatosis usually undergoes spontaneous regression within 3 months, and the dog is then immune to reinfection.[7] Oral administration of retinoids has been reported to be effective in the treatment of canine inverted papillomas,[12] and anecdotal reports indicate that interferon may be effective in the treatment of severe oral or cutaneous viral papillomatosis.[13]

182.2.2 Intracutaneous Cornifying Epithelioma

Intracutaneous cornifying epitheliomas (keratoacanthomas) arise from the outer portion of the hair follicle. They usually occur in relatively young, purebred dogs. Most are solitary, but generalized forms exist. Norwegian elkhounds and keeshonds are predisposed to the generalized form.[14] These tumors often have a

central pore filled with inspissated keratinous material. Gentle digital pressure applied to the mass results in expulsion of a gray-white keratinous material.

Intracutaneous cornifying epitheliomas are benign and do not recur after adequate surgical removal. In the generalized form, new tumors may develop throughout a dog's life. Oral retinoids may be useful in the treatment of multiple intracutaneous cornifying epitheliomas. In one study of seven dogs, five complete remissions and two partial remissions occurred.[12] Spontaneous regression has also been reported to occur in a dog with the generalized form.[15]

182.2.3 Canine Squamous Cell Carcinoma

Squamous cell carcinoma (SCC) is a common malignant neoplasm in the dog. The etiology usually is not known. Tumors that develop in unpigmented or lightly pigmented skin, such as the abdomen and inguinal areas, are believed to be induced by ultraviolet radiation (sun damage).[16] Occasionally SCC may be caused by burns, chronic infectious or immune-mediated diseases, or progression from viral papillomas.[13,17] In an immunohistochemistry study of 40 dogs with SCC, 100% of lesions showed expression of cyclo-oxygenase-2 (COX-2).[18] COX-2 has been implicated in the oncogenesis of various human cancers, but the precise mechanisms leading to upregulation of COX-2 are not known.

SCC in the dog may be proliferative, ulcerative, or erosive. The clinical features and management of canine SCC are highly dependent on the anatomic location.

182.2.3.1 Canine Cutaneous Squamous Cell Carcinoma

Cutaneous SCC may first be diagnosed as a preneoplastic lesion, but it ultimately progresses to an invasive tumor. Rarely, metastases to regional lymph nodes and the lungs may occur.[19] Canine cutaneous SCC is best managed with adequate surgical excision. Preneoplastic lesions may be responsive to oral retinoids,[16] and intralesional therapy with sustained-release cisplatin, 5-fluorouracil, or carboplatin may have a role in the management of some dogs with superficial SCC.[20] Aggressive surgical excision is the treatment of choice for invasive cutaneous SCC. Radiation therapy for incompletely excised tumors and chemotherapy with platinum drugs or doxorubicin for metastatic tumors can be considered, but their efficacy is unproven.

182.2.3.2 Canine Nasal Planum Squamous Cell Carcinoma

Nasal planum SCC can be treated with aggressive surgical excision of the nasal planum and premaxilla, but the prognosis is extremely guarded. Case selection is important when this procedure is considered. In a study of six dogs treated surgically, two recurred in less than 2 months, probably because of incomplete resections.[21] The results of radiation therapy for SCC in this location have been largely disappointing. In one study, all seven dogs treated with radiation for incompletely excised tumors suffered recurrences in 8 to 12 weeks.[21]

182.2.3.3 Canine Digital Squamous Cell Carcinoma

SCC originates from the subungual epithelium or occasionally from other tissues of the digit and is the most common digital tumor in dogs. Approximately 80% of digital SCCs invade bony tissue of the third phalanx.

Metastases are uncommon at initial diagnosis but may be diagnosed in as many as 30% of dogs after treatment. Rarely, dogs may develop SCC on multiple digits, either simultaneously or over time.[22] Wide amputation that includes disarticulation of the first phalanx and metacarpal or metatarsal bone is the treatment of choice. In one study, the 1-and 2-year survival rates were 95% and 74%, respectively, for 19 dogs with SCC arising from the subungual epithelium; the rates were 60% and 40%, respectively, for 10 dogs with SCC arising from other parts of the digit.[22]

182.2.4 Feline Squamous Cell Carcinoma

As with dogs, SCC in cats occurs most frequently in sun-damaged skin and is usually preceded by actinic (solar) keratosis.[13] Viruses may also be underlying etiologies for feline SCC. In one study, 24% of cats infected with feline immunodeficiency virus (FIV) developed SCC.[23] It is unclear whether a direct causal relationship exists, or whether the condition is due to outdoor sunlight exposure in these cats. Papillomavirus has been identified in lesions of multicentric SCC in situ (Bowen's disease).[11]

182.2.4.1 Feline Cutaneous Squamous Cell Carcinoma

Cutaneous SCC in the cat usually starts as a crusted area that eventually develops into an erosive or ulcerative lesion. The most common sites are unpigmented areas exposed to sunlight, including the external nares, pinnae, eyelids, and lips. Multiple lesions occur in approximately 45% of affected cats.[24] Metastases are rare.

Several treatment options exist for feline cutaneous SCC, including aggressive surgical excision (“pinnectomy,” “nosectomy”), cryotherapy, external beam radiation, strontium-90 plesiotherapy, photodynamic therapy, and intralesional chemotherapy. These treatments are most successful in small (less than 5 cm), superficial lesions, therefore early diagnosis and prompt therapy are essential. Small, minimally invasive SCC lesions can be controlled for longer than 1 year in most cats, and long-term control (e.g., 2 to 7 years) is possible in 10% to 60%. Treatment of larger (greater than 5 cm) or more invasive tumors is disappointing, with control times generally less than 2 years.[24–28] In all cats, avoidance of sunlight is important to prevent additional lesions.

182.2.4.2 Feline Multicentric Squamous Cell Carcinoma in Situ (Bowen's Disease)

Bowen's disease is a condition of small, plaquelike, crusted SCC lesions that histologically do not invade the basement membrane. Unlike solar-induced SCC, multicentric SCC in situ is found in haired, pigmented areas and may be caused by infection with a papillomavirus.[11] Lesions are multifocal over the head, neck, thorax, abdomen, and limbs. Occasionally focal areas of invasive SCC may be present. When possible, surgical excision is the treatment of choice. Strontium-90 plesiotherapy may be effective for lesions less than 5 mm in diameter.[11] Therapy with oral retinoids is variably successful.[11]

182.2.5 Basal Cell Tumors

Basal cell tumors are benign neoplasms that arise from the basal cells of the epidermis. They are the most common skin tumor affecting the cat.[29] The tumor previously classified as basal cell tumor in the dog has been reclassified as trichoblastoma. Basal cell tumors are usually solitary, firm, rounded, and well circumscribed.

Occasionally they may be cystic. Basal cell tumors are often pigmented, which can lead to a clinical misdiagnosis of melanoma. Adequate surgical excision is the treatment of choice.

182.2.6 Basal Cell Carcinoma

Basal cell carcinomas are usually solitary and similar to basal cell tumors; they are often pigmented brown/black. This tumor is locally invasive, therefore clinical management should include wide surgical excision. Animals with proven metastases have rarely been reported.[30] Adjunctive radiation therapy can be considered when adequate surgical margins cannot be achieved.

182.2.7 Trichoepithelioma

Trichoepitheliomas are benign neoplasms derived from the hair follicle sheath. They are relatively common in the dog and uncommon in the cat. Surgical excision is the treatment of choice. Malignant trichoepithelioma with metastases to lymph nodes and lungs has rarely been reported.

182.2.8 Pilomatricoma

Pilomatricomas are uncommon, benign tumors that arise from the hair follicle. They usually are solitary and well circumscribed. On cut section, the tumor consists of several layers of gray-white chalky tissue. Surgical excision is the treatment of choice. Rare cases of malignant pilomatricomas have been reported. Lymphatic invasion is seen histologically, and metastases to lymph nodes, the lungs, and the nervous system may occur.[31]

182.2.9 Trichoblastoma

Trichoblastomas are common benign tumors that predominately derive from primitive hair germ epithelium. This neoplasm was previously classified as basal cell tumor. Trichoblastomas are generally solitary and may be pigmented. Surgical excision is curative.

182.2.10 Other Follicular Tumors

Other uncommon follicular tumors include tricholemmoma, trichofolliculoma, dilated pore of Winer, and warty dyskeratoma. These are benign lesions, and adequate surgical excision should be curative.

182.2.11 Sebaceous Gland Tumors

Sebaceous gland tumors are derived from sebocytes and are among the most common skin tumors in dogs. They are uncommon in cats. Histologically, they are classified as sebaceous hyperplasia, epitheliomas, adenomas or, rarely, carcinomas. The lesions are wartlike or cauliflower-like in appearance and can occur throughout the body, including on the eyelids. They are usually solitary, but multiple sebaceous gland tumors can occur.

Surgical excision is the treatment of choice for all types of sebaceous gland tumors. Local recurrence is rare, but up to 10% of dogs may develop lesions at other sites.[32] Dogs with sebaceous hyperplasia may respond to therapy with oral retinoids.[12] Sebaceous carcinomas appear to have a low potential for metastasis.[32]

182.2.12 Hepatoid Gland Tumors (Perianal Gland Tumors)

Perianal gland tumors arise from canine circumanal glands, which are modified sebaceous glands. They are referred to as *hepatoid glands* because the cells morphologically resemble hepatocytes. Circumanal glands contain receptors for both testosterone and estrogen, and intact males are at increased risk for tumor development. The occurrence of these tumors in female dogs or in males that were castrated early in life suggests a need for evaluation for hyperadrenocorticism. The vast majority of perianal gland tumors are benign and histologically may include hyperplastic lesions, adenomas, or epitheliomas. Rarely, hepatoid gland carcinomas occur.

Most perianal gland tumors occur adjacent to the anus, but they can also occur on the ventral aspect of the tail and perineum. Fine needle aspiration cytology may help differentiate perianal gland tumors from other tumors of the perineum; however, it may be difficult to distinguish adenomas from carcinomas.

Castration is the treatment of choice for perianal gland hyperplasia and adenomas in intact males; 95% of lesions regress. Surgical excision is necessary in female dogs and castrated animals or when the tumors are ulcerated. Radiation therapy may cause nonresectable adenomas to regress, but limited information is available on this treatment.

Carcinomas do not regress after castration, therefore aggressive surgical excision must be done. In one study, 70% of dogs with tumors less than 5 cm in diameter survived for 2 years when treated by surgical excision alone.[33] Ten percent to 30% of tumors may metastasize to the iliac lymph nodes, liver, and lungs.[34] Radiation therapy can be considered for tumors that are incompletely excised or if metastasis to iliac lymph nodes is confirmed. Occasionally, lymphadenectomy may be an option. Doxorubicin and platinum compounds may be useful, but their efficacy is unproven.

182.2.13 Sweat Gland Tumors (Apocrine Gland Tumors)

Sweat gland tumors in dogs and cats commonly occur in the inguinal or axillary regions. These tumors have various clinical presentations, including solitary nodular masses or a diffuse, inflammatory and ulcerative, plaquelike growth. Cats with a histologic diagnosis of apocrine gland carcinoma of the digit may actually have digital metastases from a pulmonary carcinoma.

The majority of sweat gland tumors are histologically malignant (carcinomas), and more than 20% may have evidence of lymphatic or vascular invasion.[35,36] Wide surgical excision is the treatment of choice. In two retrospective studies, fewer than 2% of canine sweat gland carcinomas developed distant metastases.[35,36] Metastatic disease may have been correlated with intravascular invasion.[36]

182.2.14 Ceruminous Gland Tumors

Ceruminous gland tumors originate from modified apocrine sweat glands found in the external ear canal. Chronic otitis may be a predisposing factor.[37] Common clinical signs associated with ear canal tumors include the presence of a mass, aural discharge, odor, pruritus, and pain. Neurologic signs, including Horner's syndrome and vestibular disease, may also be present. Radiographs of the skull and/or computed tomography are important imaging modalities that should precede surgery. Careful evaluation of the mandibular and periauricular lymph nodes is essential.

Ceruminous gland adenomas can be managed by conservative surgical resection. For ceruminous gland carcinomas, however, aggressive surgical excision, including ear canal ablation and lateral bulla osteotomy, is the treatment of choice. Sixteen cats treated by ear canal ablation and bulla osteotomy had a 42-month median remission, a 25% recurrence rate, and a 75% 1-year survival rate. Six cats treated only with lateral ear resection had a 10-month median remission, four of the cats had recurrence, and the 1-year survival rate was only 33%.[38] In seven dogs, aggressive ear canal ablation with lateral bulla osteotomy resulted in no recurrences during follow-up for a median of 36 months, compared with a 75% recurrence rate within 4 months for four dogs treated by a more conservative lateral ear canal resection.[39]

750

751

Radiation therapy can be used as an adjunct to incomplete resection. A median progression-free interval of 40 months and a 56% 1-year survival rate were achieved in one study of six cats and five dogs treated with radiation therapy after incomplete resection of ceruminous gland adenocarcinoma.[40]

182.2.15 Anal Sac Adenocarcinoma

Anal sac adenocarcinomas arise from the apocrine glands in the ventrolateral aspects of the anus. They occur almost equally in female and male dogs but are rare in cats. The tumors are usually unilateral, occasionally can be bilateral, and are either discrete or infiltrative when palpated rectally. Twenty-five percent to 50% of anal sac adenocarcinomas produce parathyroid hormone–related protein (PTHrP), leading to hypercalcemia of malignancy.[41,42] Metastases generally arise in the iliac lymph nodes, although distant metastases may also be seen in the liver, spleen, lungs, and other sites. Occasionally extension from the iliac lymph nodes into the lumbar vertebrae may occur.[42]

Aggressive surgical excision with or without chemotherapy and radiation therapy is recommended for treatment of anal sac adenocarcinoma. Hypercalcemia generally resolves quickly after resection of the primary tumor. The rate of local recurrence after surgical excision is approximately 50%. It is unclear whether this correlates with incomplete histologic margins.[41,42] In one study, dogs underwent surgical excision of the primary mass. Some also had surgical removal of metastatic lymph nodes. The median survival for dogs with metastases (n = 11) or hypercalcemia of malignancy (n = 5) was 6 months, compared to 15.5 months for dogs without metastases (n = 10) and 11.5 months for dogs with normocalcemia (n = 16).[41] In another study of 34 dogs, the overall median survival was approximately 8 months.[42]

Adjunctive treatment with radiation to the anal sac and iliac lymph node regions and chemotherapy with platinum agents or doxorubicin may improve outcome. However, this has not been substantiated.

182.3 ROUND CELL TUMORS

Round cell tumors may also be called *discrete cell tumors*. Cytologically, they appear as individually oriented, round cells that have no obvious attachments to each other. The round cell tumors include lymphoma, mast cell tumors, plasmacytomas, histiocytomas, and transmissible venereal tumors. Occasionally melanomas and basal cell tumors may mimic round cell patterns.

182.3.1 Lymphoma, Mast Cell Tumor, Histiocytoma, and Transmissible Venereal Tumor

For a discussion of these tumor types, the reader is referred to detailed information presented in other chapters of this text.

182.3.2 Plasmacytoma

Cutaneous plasma cell tumors (cutaneous extramedullary plasmacytomas) are usually solitary, and common locations of occurrence are the digits, lips, pinnae, oral cavity, and rectum.[43,44] The majority of cutaneous plasmacytomas in the dog are benign and are unrelated to multiple myeloma. The behavior of canine plasmacytomas does not seem to have any relationship to the degree of histologic atypia or pleomorphism.[43,44]

The treatment of choice for cutaneous plasmacytomas is surgical excision. Local recurrence may be associated with incomplete margins.[43] Radiation therapy can be considered for cases that are nonresectable, but information is limited.

182.4 MELANOCYTIC TUMORS

182.4.1 Melanoma

The etiology of cutaneous melanomas in dogs and cats is unknown, but breed predilection in dogs suggests a genetic basis. Breeds reported to be at risk include Scottish terriers, Airedales, Boston terriers, cocker and springer spaniels, boxers, golden retrievers, miniature schnauzers, and Doberman pinschers.[13] In dogs, lesions are usually solitary and are brown to black in appearance. Common sites include the eyelid, muzzle, trunk, interdigital skin, and subungual epithelium (nail bed). Digital melanomas are the second most common digital tumor in dogs, next to squamous cell carcinoma. In cats, the most common pigmented cutaneous tumor is a basal cell tumor. However, melanomas also are black. Common sites in cats include the pinna, nose, and neck.

Cutaneous melanomas can be behaviorally benign or malignant. Of critical importance is the location of the tumor. As a general rule, tumors arising from the haired skin are benign. Those arising from mucocutaneous junctions are malignant, the only exception being those arising on the eyelids. Melanomas of the digit may be highly malignant. Malignant melanomas commonly spread via lymphatics to draining lymph nodes and the lungs. Metastases to distant sites such as the liver, spleen, brain, heart, and bone marrow occasionally occur.

In dogs, the histologic mitotic index is highly predictive of biologic behavior.[45–47] A mitotic index of less than 3 per 10 high-power fields is generally associated with benign behavior.[45] It is difficult to predict the biologic behavior of cutaneous melanomas in cats based on the mitotic index, because 25% of malignant tumors may show no mitotic figures.[48]

The treatment of choice for cutaneous melanomas in both the dog and the cat is surgical excision. In one study, 59 dogs had a median survival of 26 months and a 2-year tumor-related death rate of 10% if the mitotic index of the tumor was less than 3. In contrast, 26 dogs had a median survival of 7.5 months and a 2-year tumor-related death rate of 73% if the mitotic index of the tumor was 3 or higher.[45] With digital melanomas in dogs, more than 50% may develop metastases. A median survival time of 12 months has been reported for dogs treated by amputation of the affected digit.[22] Other studies have reported median survival times of 18 to 24 months.[45,46]

The prognosis for cats with cutaneous melanomas is guarded. In one study of 57 cats with the tumors, metastases were documented at initial diagnosis in 11 (19%). Forty-five cats were treated by surgical excision, and 22 of these animals developed local recurrence or metastases.[49]

Coarsely fractionated radiation therapy is useful for treating dogs with oral melanoma and may be beneficial for local control of nonresectable cutaneous melanomas in dogs and cats.[50] Also, a clinical response to treatment with carboplatin can be seen in dogs with oral melanomas, therefore this may be considered as an adjunct therapy in dogs with digital melanomas or in dogs and cats with malignant or nonresectable tumors or metastatic disease.[51]

183 CHAPTER • 183 Soft Tissue Sarcomas

Rodney L. Page

Margaret C. McEntee

Soft tissue sarcomas represent a significant group of cancers in companion animals. Collectively, sarcomas include numerous histologic subcategories that are derived from neoplasms of mesenchymal origin. Box 183-1 lists the individual histologic categories of canine soft tissue sarcomas included in most discussions. In some instances, distinct biologic behaviors have been described for specific subcategories. However, the collective experience of pathologists and specialists managing sarcomas in dogs has permitted development of a histologic grading scheme that more uniformly describes clinical behavior by the degree of differentiation rather than specific histologic type (Table 183-1). The histologic grade of a tumor can dictate radical versus functional surgery or may determine the addition of radiation therapy or chemotherapy. In addition, the size of the tumor and its location will obviously affect the surgical options available for local control. Despite the general consensus that grade may influence the ultimate control of a tumor, debate continues about the universal applicability of histologic grade of sarcomas as a clinically meaningful predictor of response in dogs. To date, no convincing evidence exists for comparison of grade with outcome for feline sarcomas. Specific histopathologic types of sarcomas include fibrosarcoma, undifferentiated sarcoma, osteosarcoma, rhabdomyosarcoma, liposarcoma, malignant fibrous histiocytoma (or myofibrosarcoma) and leiomyosarcoma. Hemangiosarcomas (HSAs), synovial cell sarcomas, and mast cell tumors (MCTs) are discussed separately in this text due to the common occurrence of these cancers and their unique biologic and clinical features. Other, less common sarcomas are not included, because they cannot be considered as part of the collective terminology due to insufficient information (e.g., rhabdomyosarcoma).

Soft tissue sarcomas are typically focal, solitary, palpable, soft to firm lumps found in the dermis, subcutaneous tissue, or deeper muscular and musculofascial compartments. The most common owner concern is the identification of a palpable or visible nonpainful mass (or both) that may be growing. Masses that have grown rapidly or have been present for a prolonged time with resultant substantial growth can have an ulcerated surface and may be painful. The majority of masses are 2 to 4 cm in diameter at the time of initial examination. Tumor size can vary depending on a number of factors including location on the body, particularly whether it is located superficially in the dermis or deep in a muscle, whether an owner frequently handles or grooms the pet and identifies a new lump early, the overall body condition with masses more easily observed on a trim pet, and the length and thickness of the hair coat. Soft tissue sarcomas can develop in any location on the body but are most commonly identified on the limbs or head. In cats, soft tissue sarcomas are frequently associated with sites of previous vaccination and therefore are more commonly located on the trunk either in the interscapular region, dorsal lumbar, or flank region.

Schwannoma

An accurate diagnosis is critical for appropriate treatment planning. An incisional biopsy is recommended for all but the smallest of nodules to prevent disruption of the surrounding normal tissue prior to definitive surgical planning. Excisional biopsies should be avoided unless the mass is small (<1 to 2 cm proportional to the size of the dog or cat) and surrounded by abundant normal tissue. In addition, all biopsy procedures should be carefully planned for all subcutaneous nodules to avoid inadvertent contamination of surrounding tissues. Although local control is expected with complete surgical removal, local recurrence is often observed after suboptimal surgical procedures. Aggressive tumor management at the first opportunity is required for successful management of soft tissue sarcomas. The challenge of surgical planning, the need for multimodality therapy in many instances, and the potential for metastases despite local control in high-grade sarcomas add complexity to the treatment decision-making process. These challenges are particularly important for successful management of injection-site sarcomas in cats.

183.2 CAUSE

The genetic or specific biochemical mechanisms responsible for development of sarcomas in both dogs and cats remain unknown. It is believed that most sarcomas that develop in dogs occur sporadically. Germ-line mutations

or familial forms of sarcomas have been confirmed in humans, and provocative anecdotal epidemiologic evidence suggests similar processes may be present in dogs. However, detailed genetic or pedigree characterization of dogs that develop sarcomas at a young age (<2 years) or where a breed prevalence seems likely have not been conducted. In one recent study, chromosomal translocation was identified in 1 of 30 canine sarcomas, although its significance remains unknown.[1]

It is well established that exposure to irradiation, viral infection (feline sarcoma virus), trauma, or chronic inflammatory conditions are associated with development of sarcomas in dogs and cats. Conventional irradiation schedules for management of a primary cancer carries less than 5% risk of a radiation-induced tumor occurring 3 to 5 years later.[2] Clearly, the benefits of primary tumor control outweigh the risk of radiation-induced second tumors. High, single doses of radiation used for intraoperative therapy are more likely to produce sarcomas (20% to 25%) in dogs with a median latency of 4 years postirradiation.[3]

The molecular development of injection-associated sarcomas in cats is not yet defined. There have been several reports eliminating the most common feline viral infections (oncorna, papilloma, polyoma viruses) as causes.[4–6] Unique molecular features of injection-associated sarcomas have been identified. Epidermal growth factor/receptor (EGFR), platelet-derived growth factor/receptor (PDGF), and transforming growth factor–beta expression is abundant on tumor cells and infiltrating lymphocytes in injection-site sarcomas but are not expressed in cells from noninjection site sarcomas of cats.[7] C-Jun overexpression, a proto-oncogene, has also been identified in feline injection site sarcomas and may be the result of persistent growth factor stimulation.[7]

P53 abnormalities have been reported in vaccine-associated sarcomas. In one report, approximately 43% of samples from sarcomas strongly overexpressed the p53 protein.[8] In another report, five of eight tumor samples overexpressing this protein had a mutated gene. No cats from a control group of 13 injection sarcomas without p53 protein overexpression had gene mutations.[9] In this study, no surrounding tissue had p53 mutations, suggesting that abnormalities in p53 function did not exist prior to tumor development. These data taken collectively indicate that molecular and cellular abnormalities exist and suggest several hypotheses; however, no specific cause has been associated with the development of feline injection sarcomas.

Abnormalities in p53 and MDM2, a gene with a product that suppresses p53 expression, have recently been reported in canine sarcomas.[10] Twenty percent (6/30) of sarcomas had base substitutions resulting in single amino acid misreads in the p53 gene. Three of these six tumors with mutations were malignant nerve sheath tumors. Interestingly, canine MDM2 gene amplification (threefold or greater) was identified in five of the 30 sarcomas. In all but one of these combined samples there was coordination of these abnormalities, resulting in p53 disruption (mutations) or secondary p53 suppression due to MDM2 overexpression. Thus directly or indirectly, almost one third of canine sarcomas appear to have altered p53 function. Interestingly, five of seven malignant peripheral nerve sheath tumors had p53 functional abnormalities.

183.3 INITIAL CLINICAL EVALUATION

Routine evaluation of the patient should be conducted, including a thorough physical examination and laboratory evaluations. Tumor staging includes the assessment of the extent of local disease and detection of any evidence of regional or distant metastasis. A thorough description and measurement of the mass in three dimensions is essential and is important for documenting subsequent growth if initiation of therapy is delayed, or for documentation of therapeutic response. Soft tissue sarcomas, in general, have a relatively low metastatic rate, but the rate of metastasis increases with increasing tumor grade. The greatest concern of metastasis is with high-grade

sarcomas. The regional lymph node should be evaluated by aspiration, biopsy, or both techniques, particularly if the lymph node is enlarged or if it is a high-grade tumor. Metastasis can occur to the regional lymph node, although this is not the most common site of metastasis. The incidence of metastasis for sarcomas at initial diagnosis is low, but without specific examination of regional lymph nodes or careful follow-up, the actual incidence of metastasis remains unknown. The most common route of metastasis is via the hematogenous route, and the most common sites of metastasis are the lung and liver. In cats with vaccine-associated fibrosarcomas, sites of metastasis that have been reported include lung, skin, or subcutaneous sites, regional lymph nodes, mediastinum, liver, and pelvis.

Appropriate imaging for evaluation of the primary tumor, as well as thoracic radiographs and abdominal ultrasound, should be conducted during the staging process if malignancy is confirmed. Imaging techniques may also aid in planning biopsy and treatment options. An ultrasound evaluation of the primary tumor may aid in determining the best site for biopsy; for deep-seated tumors, ultrasound guidance may be necessary for accurate tumor sampling. Imaging of soft tissue sarcomas increasingly involves more advanced cross-sectional imaging studies such as computed tomography (CT) or magnetic resonance imaging (MRI). CT with the administration of intravenous contrast can assist in delineating the extent of the local disease and extension into the surrounding tissues. It is highly recommended that imaging precede therapeutic intervention. The extent of invasion into surrounding tissues for vaccine-associated sarcomas in cats can be substantial, and an initial excisional biopsy can impair the ability to achieve local tumor control. It was recently determined that tumor volume measured from contrast-enhanced CT studies of feline sarcomas exceeded the physical measurements by two-to fivefold, and attachment of the tumor to surrounding muscle and tissue was much more extensive than predicted.[11] Figure 183-1 illustrates an infiltrative sarcoma in the prescapular and interscapular space of a cat. Obviously, a surgical procedure without accurate knowledge of tumor extent in feline injection sarcomas is not recommended. Furthermore, in dogs, soft tissue sarcomas frequently occur on the extremities where it is difficult to resect the tumor with the necessary margins. An initial biopsy and imaging can provide both a diagnosis and understanding of the extent of disease, with preplanning possible so that an owner can be appraised of whether or not combination therapy may be indicated, with the potential for increased duration and cost of therapy.

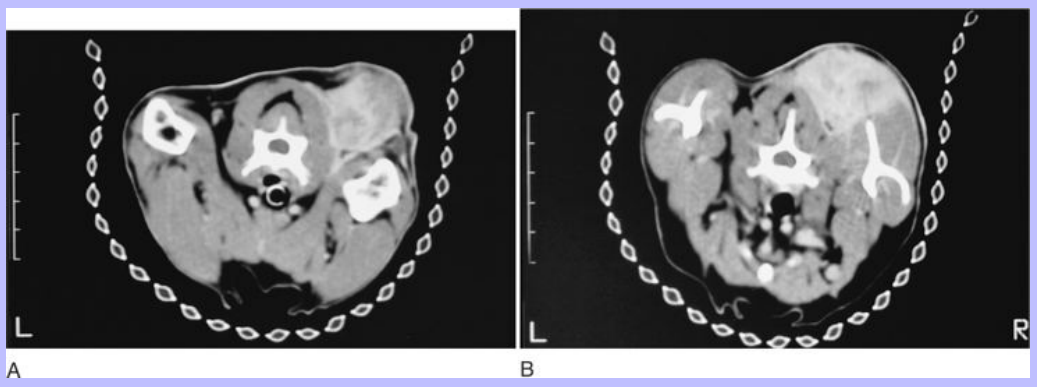
183.4 BIOPSY CONSIDERATIONS

As with any suspected tumor, the clinician needs a definitive diagnosis to determine the best treatment strategy. Aspiration cytology can provide initial information on a dermal or subcutaneous lump that may support the diagnosis of a non-neoplastic process. Additionally, aspiration cytology can be diagnostic for neoplasia and indicative of a round cell (e.g., MCT), epithelial or mesenchymal tumor. Mesenchymal tumors are less likely to exfoliate during aspiration, and for soft tissue sarcomas, aspiration cytology is performed primarily to rule out other disease processes. At times, cytology may be diagnostic for a sarcoma. An incisional biopsy is recommended to obtain a definitive diagnosis of a soft tissue sarcoma and to determine the specific histopathologic type. The biopsy procedure for sarcomas should be carefully planned to obtain a representative sample of the tumor and prevent any unnecessary complications or contamination of surrounding tissue with tumor. If a cutting needle is to be used, care should be taken not to penetrate beyond the known tumor perimeter. Sarcomas are often adhered to adjacent tissue, and extension along fascial planes can be difficult to appreciate on physical examination. Therefore biopsy samples such as those obtained from limited incisions, punch biopsy tools, or cutting needles are preferred to excisional biopsy to minimize any tissue disruption. The acquisition of a biopsy sample allows grading of the tumor based on assessment of a number of histopathologic features. The histologic features assessed in soft tissue sarcomas to arrive at a tumor grade include degree of differentiation, percentage of necrosis, and mitotic rate (see Table 183-1). Tumor grade for soft tissue sarcomas in dogs can have prognostic significance with a more progressive course and higher likelihood of metastasis with a high-grade tumor. One report on prognosis in cats after surgical excision of fibrosarcomas showed a correlation between mitotic index (sum of mitotic figures in

753 754

ten high-power fields) and median survival. For cats with a mitotic index less than six the median survival was 32 months as compared with 4 months if the mitotic index was greater than or equal to six. More recent studies have not shown a correlation between tumor grade and survival in cats with vaccine-associated sarcomas. Such tumors may have a cell population that is generally more aggressive than many other sarcomas.

Figure 183-1 Computerized tomography (CT) image with contrast agent of a feline vaccine-associated sarcoma in prescapular space. Extensive soft tissue infiltration is obvious with numerous muscles adjacent to tumor tissue.



183.5 GENERAL TREATMENT CONSIDERATIONS

Surgical excision of any tumor without preplanning can result in incomplete removal and the need for a second, more extensive surgical procedure, radiation therapy, and potentially a higher complication rate. Soft tissue sarcomas in particular are likely to be incompletely removed with close marginal excision due to tumor extension beyond what is visible. Higher morbidity and cost associated with incomplete resection justify the referral of pets with large or high-grade soft tissue sarcomas for consideration of multidisciplinary evaluation and possibly multimodality therapy. Figure 183-2 represents a decision-making algorithm for soft tissue sarcomas, or any superficial nodule, based on the initial determination of surgical success. Pivotal decision points in this algorithm include the determination of whether curative surgery is possible, the success of the surgical procedure based on thorough evaluation of the surgical margins, and the need for any adjuvant chemotherapy determined by tumor grade and stage.

Decision regarding surgical resection of a soft tissue sarcoma is perhaps the most critical point in the algorithm. The decision to attempt resection should be made from accurate measurement of the mass and its deep tissue attachments, the location of the tumor and surrounding normal tissue limitations for deep resection, and the surgeons' skill. The surgical procedure should be well planned to accomplish the goal of complete resection and reduce or prevent the likelihood of inadvertent seeding of the tumor resection bed and surrounding tissue. Referral to a surgical specialist that has had extensive experience with cancer surgery should be considered for most sarcomas. New techniques are being evaluated and implemented that require advanced technology and training.[12]

After a surgical procedure it must be assumed that the entire operating field could be contaminated, including the scar. The use of appropriate technique is essential. This includes incision planning, avoidance of unnecessary manipulation of the tumor itself, or placement of drains with distant tissue dissection. During the procedure,

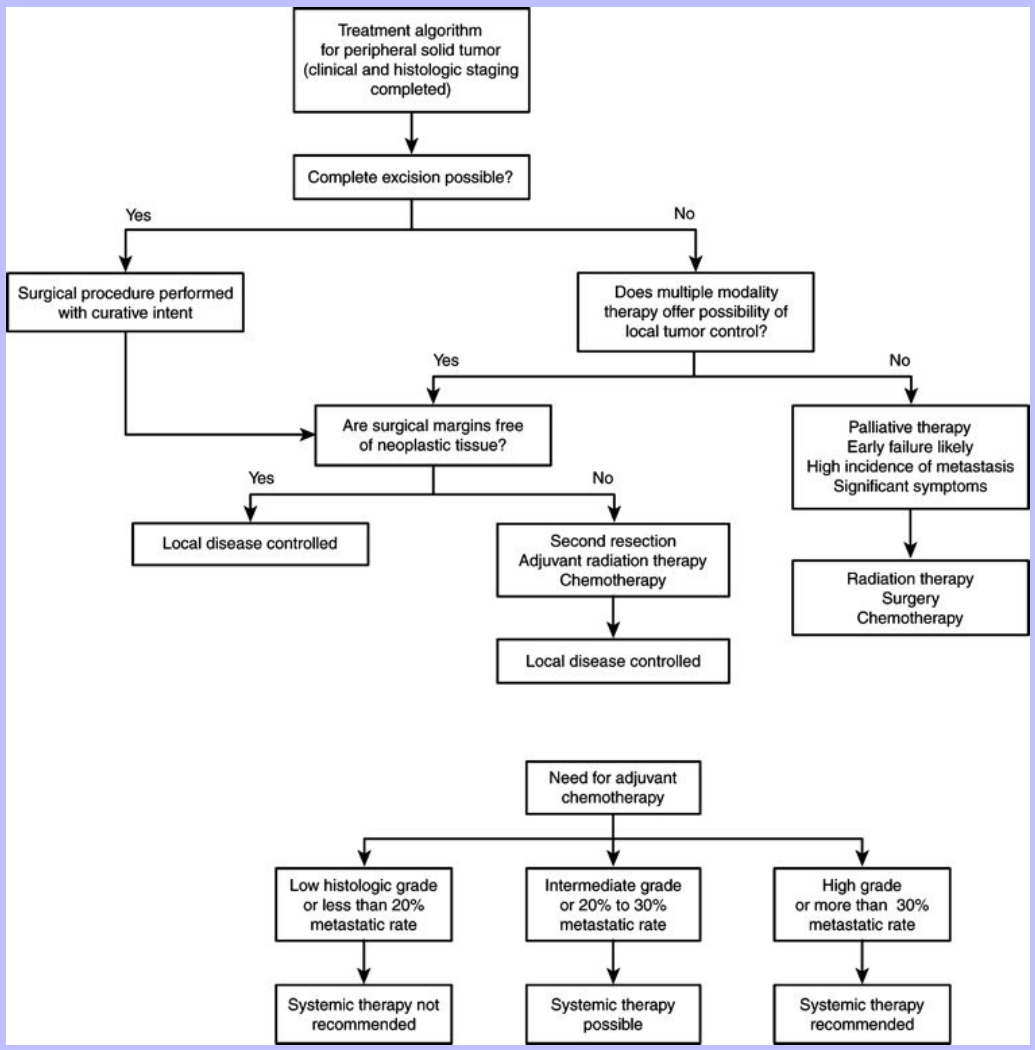
hemoclips may be used to define the deep and lateral extent of the surgical plane. This will be of benefit to determine the area of resection if a second surgery is indicated or for radiation treatment planning if needed.

Examination of the deep margins for completeness of resection is of critical importance for determining local tumor control. The histopathologic analysis of tumor margins is aided by deep surface marking with permanent dye and a thorough description of the sites that might be suspect for closer examination by the pathologist.[13–15] Adequate margins around the tumor tissue can be difficult to estimate once the tissue has been processed for fixation and microscopic evaluation. For classification of complete resection, most pathologists recommend a minimum of ten cell diameters between tumor and deep surface. This arbitrary designation should be carefully examined with more defined measurements of distance that could be correlated to the required margin necessary to prevent recurrence for different grades of sarcoma.

754

756

Figure 183-2 Soft tissue sarcomas.



Palliative therapy may be necessary for tumors that are not amenable to aggressive surgery or multimodality therapy. Palliative therapy should be actively pursued, and numerous treatment options have been devised specifically for management of dogs and cats with noncurable tumors or those with significant signs associated with the presence of tumors.

183.6 MANAGEMENT OF CANINE SOFT TISSUE SARCOMAS

To date, no known risk factors exist for the development of canine sarcomas. Therefore general recommendations for cancer screening and detection such as frequent physical examinations, radiographs, and other imaging studies should become more routine for earlier identification of sarcomas. Any mass that is apparent should be characterized early with measurements, appropriate imaging, and biopsy. If a sarcoma is identified, the procedures outlined previously for treatment planning should be implemented.

Figure 183-2 summarizes the treatment recommendations for management of the primary tumor and whether chemotherapy for adjuvant treatment should be instituted after local control. Surgical resection should be the first consideration for any sarcoma. The conclusion that a mass is potentially curable with surgery should be closely scrutinized because local recurrence represents a serious complication of inadequate surgery and will impact future treatment options.[16] Referral for more extensive tumor evaluation and aggressive management is warranted for tumors occurring in areas of complex musculofascial anatomy because adequate normal tissue removal around the sarcoma improves local control.[17] Multimodality therapy is an appropriate consideration for tumors that are not easily resectable.

Radiation therapy has been shown to be of significant benefit for local control in tumors that are not controllable with surgery alone. The use of preoperative or postoperative irradiation can be considered, although ideally, the schedule for application of radiation therapy should be made before the treatment is initiated rather than using radiation as a means to manage residual disease after an inadequate surgical procedure.[18] Several studies have demonstrated that irradiation results in long-term control of soft tissue sarcomas in dogs.[19,20] Local relapse-free survival has been estimated at 75% to 85% for 3 or more years, and this combination should be recommended for all incompletely excised sarcomas in dogs. Current treatment schedules and technology make irradiation of tumor sites less likely to result in limiting side effects than previous techniques. However, soft tissue sarcomas can arise in any tissue, and adjacent normal structures can be difficult to avoid in some instances without compromising tumor control.

Chemotherapy also has a role in management of canine soft tissue sarcomas. A recent review thoroughly describes the indications, options, and strategies for chemotherapy in sarcoma management.[21] Chemotherapy is indicated when animals have inoperable sarcomas because of size or location because a measurable reduction might allow function-preserving resection; pets with recurrent sarcomas that are not amenable to second surgical procedures; dogs with high-grade sarcomas to reduce or delay metastatic nodules; and those with sarcomas that have inherently greater likelihood of metastasis such as oral sarcomas, liposarcomas, and dogs with soft tissue sarcomas of the spleen. Adriamycin is the most active single agent for canine sarcomas.[21] Other options include platinum-containing agents and ifosfamide. Although no definitive evidence exists to make adjuvant chemotherapy a general recommendation for dogs with high-grade sarcomas, many specialists feel the chance for distant spread of the tumor even with local control (~40%) warrants a recommendation of treatment with chemotherapy.[17]

Palliative therapy is also available for dogs with tumors that have significant functional abnormalities directly related to the tumor. Irradiation schedules for palliative management are designed to deliver a significant dose to the tumor without debilitating side effects and with minimal hospitalization. Tumors associated with dysphagia, dyspnea, dyschezia, or dysuria, and that are assumed to be incurable with surgery should be considered for palliative irradiation. Palliative chemotherapy may also be offered in hopes of reducing the mass associated with debilitating clinical symptoms. Any response to treatment should be observed after the initial treatment course and is unlikely to occur after the second course of treatment. Therefore continuation of the chemotherapy is unnecessary if no response is observed. Surgical procedures designed specifically for improved quality of life in dogs with extensive disease include resolution of ulceration and management of secondary infection.

183.6.1 Management of Canine Soft Tissue Sarcomas with Unique Clinical Features

The majority of tumors listed in Table 183-1 can be managed with the principles described after considering the histologic grade and the likelihood of local control. Special consideration should be given to several sarcomas due to unique presentations or tumor biology. Discussion of synovial cell sarcoma, malignant fibrous histiocytoma, and HSAs are discussed in chapters 181, 184, and 187.

183.6.1.1 Leiomyosarcoma

Sarcomas of smooth muscle occur most often in the intestinal tract and are singled out here due to special considerations of management related to their site of origin. Because second approaches are unlikely, it is recommended that intestinal tumors be resected widely and any lymph nodes or other sites of concern in the abdomen be resected to aid in staging during the laparotomy. Several retrospective reviews have reported clinical outcome of approximately 100 dogs with leiomyosarcoma of the intestine.[22–24] In addition, data is available describing the site or origin and metastases of 158 dogs and 22 cats with leiomyosarcomas.[25] Leiomyosarcomas are most often located in the small intestine, cecum, spleen, or urogenital tract. Feline leiomyosarcomas are uncommon but occur in the intestinal tract more often than other sites. If complete surgical resection can be accomplished, median survival times (MSTs) are approximately 18 to 21 months, and many dogs succumb to diseases other than recurrence or metastasis. Metastatic lesions are reported in 15% to 30% of dogs with leiomyosarcomas and are most likely to be found in the mesentery, spleen, or liver. Metastases may be slow to develop (1 to 2 years) and relatively slow to progress to clinical signs. No reports on postoperative chemotherapy are available.

183.6.2 Management of Feline Sarcomas

Surgical excision of soft tissue sarcomas in cats represents the best chance of affecting local tumor control.[26,27] If an initial biopsy is suggestive of soft tissue sarcoma in a cat, imaging (CT or MRI) will provide the most accurate assessment of the extent of disease and assist in developing an appropriate treatment plan. An excisional biopsy of a vaccine-associated sarcoma will rarely result in a complete resection and is likely to result in local recurrence and a second, more difficult surgery will be necessary. Tumor recurrence has been documented to occur as early as 2 weeks after surgery and will typically occur by 6 months after incomplete surgical resection.[28] An aggressive surgical resection is necessary to effect local control, and this can entail resection of the tumor with 3 to 5 cm margins, removal of associated bone (e.g., dorsal spinous processes, partial scapulectomy), and at least one fascial plane deep to the involved tissues. Vaccine-associated sarcomas have commonly occurred in the interscapular space. This is a difficult location for surgery because it may require removal of dorsal spinous processes and the surrounding musculature. For this reason the

Vaccine-Associated Feline Sarcoma Task Force has made the recommendation to vaccinate with rabies and feline leukemia virus (FeLV) in the distal hind limb. Therefore amputation would be possible to effect local tumor control. Even with amputation or hemipelvectomy, it may not be possible to completely excise a vaccine-associated sarcoma. It is often necessary to use a multimodality approach, combining radiation therapy and surgery. For instance, preoperative irradiation of a proximal limb sarcoma may be necessary prior to amputation. The use of radiation therapy in the preoperative setting will often result in reduction in tumor size, and theoretically sterilization of the peripheral components of the tumor that would otherwise be problematic and result in an incomplete resection and resultant rapid tumor regrowth.

Chemotherapy may be used in the management of vaccine-associated sarcomas as adjuvant therapy to address potential metastatic disease, as neoadjuvant therapy to reduce the tumor in size prior to surgical resection, or as palliative therapy for nonresectable tumors. The use of combination doxorubicin and cyclophosphamide has been reported in 12 cats with nonresectable tumors.[29] There was a 50% overall response rate. The MST was significantly longer in those cats that responded (242 days) than in those that did not respond (83 days).

A combination of surgery, radiation therapy, and chemotherapy may result in the greatest potential for long-term tumor control. The largest report to date details the results of preoperative radiotherapy in 92 cats with vaccine-associated sarcomas.[30] The median time to first event (time from the start of treatment to local recurrence, metastasis, or date of death or euthanasia) was significantly longer at 986 days (n = 59 cats) if a complete resection was accomplished compared with 292 days (n = 28 cats) with an incomplete resection. There was a trend toward improved survival with the addition of chemotherapy (carboplatin, other) with a median time to first event of 1059 days (n = 33 cats) in cats that received chemotherapy versus 584 days (n = 59 cats) in those cats that were treated with radiation and surgery alone. The overall rate of metastasis was 21.7% (20/92), although complete follow-up was not available for all cats. Ongoing investigations are being carried out to determine the optimal treatment approach for vaccine-associated sarcomas, but it is likely that the best chance for success will lie in early detection and aggressive management or prevention of the development of vaccine-associated sarcomas.

183.7 PREVENTION

The cause of the majority of canine soft tissue sarcomas is unknown and therefore it is not feasible to develop strategies for prevention. However, for cats where there has been an association between vaccination and the development of soft tissue sarcomas, it is possible to decrease the risk of development of a soft tissue sarcoma. It is important to limit the number of vaccinations that are administered to cats and to only give those vaccines that are necessary to maintain health. For instance, it is not necessary to vaccinate cats for FeLV when they are indoor cats that are not exposed to other FeLV-positive cats. It is also important to follow the recommendations that have been provided by the Vaccine-Associated Feline Sarcoma Task Force: limiting one vaccine per site and documenting the location of each of the vaccines (right hind limb for rabies, left hind limb for FeLV, and right lateral scapular region for feline viral rhinotracheitis calcivirus panleukopenia [FVRCP]). In this way even if a tumor is to develop, an owner can be informed as to what to watch for and where to check for a possible tumor. Additionally, vaccines have been developed that do not appear to result in a local inflammatory response and may therefore translate into a decreased risk of tumor development at that site, although no long-term studies have confirmed this. There have been isolated reports of tumor development in cats at sites not associated with vaccination but rather due to some other inciting event that has resulted in a local inflammatory response. For instance, a report exists of a cat that developed a condition similar to a vaccine-associated fibrosarcoma at the site of a deep nonabsorbable suture.[31]

183.8 SUMMARY

Soft tissue sarcomas include a diverse group of histologic types classified based on the cell of origin but, as a group, exhibit similar biologic behavior. Tumor grade has proven to be important and predictive for outcome in dogs with soft tissue sarcomas but has not been shown to be of prognostic significance in cats. Wide surgical resection is required for local control in dogs and cats with soft tissue sarcomas. Radiation therapy will control the majority of tumors after incomplete resection in dogs; however, complete surgical removal, with or without irradiation, is necessary for control of vaccine-associated sarcomas in cats. Currently, a multimodality approach including surgery, radiation therapy, and chemotherapy seems reasonable to optimize the chance of tumor control in dogs with high-grade soft tissue sarcomas and cats with vaccine-associated sarcomas.

184 CHAPTER • 184 Hemangiosarcoma

Philip J. Bergman

184.1 GENERAL FEATURES, PATHOLOGY, AND BIOLOGIC BEHAVIOR

Hemangiosarcoma (HSA) (angiosarcoma, malignant hemangioendothelioma) is an extremely malignant cancer of vascular endothelial origin. With this cellular origin, virtually any anatomic site can have HSA as a primary or secondary tumor diagnosis. HSA occurs most frequently in dogs (approximately 2% of all tumors), and the most common site of origin is the spleen; however, additional sites include right atrium, pericardium, liver, muscle, lung, skin and subcutis, bone, kidney, central nervous system (CNS), peritoneum and oral cavity.[1–3]

In three large canine splenic disease studies encompassing approximately 2000 dogs, a “rule of two thirds” was found, suggesting that approximately two thirds of dogs with a splenic mass have a malignancy (therefore one third are not malignant) and two thirds of the malignant tumors of the spleen are HSA.[2,4,5] It cannot be overemphasized that only histology can confirm the diagnosis of HSA. The differential diagnosis for a splenic mass should include lymphoma, leiomyosarcoma, fibrosarcoma, osteosarcoma, malignant fibrous histiocytoma, and other sarcomas (e.g., undifferentiated, liposarcoma, mesenchymoma), as well as non-neoplastic entities such as nodular hyperplasia, splenic hematoma, and hemangioma.[4,6,7] HSA can be single or multiple, and in those dogs with multiple tumors it can be extremely difficult to identify which is the primary tumor. HSAs are typically grossly soft, nodular, and dark red due to hemorrhagic and necrotic regions; however, extremely undifferentiated HSAs can lose this grossly vascular appearance and be more firm and pale gray, like other sarcomas. Immunohistochemistry (IHC) using antibodies against factor VIII, PECAM, and other antigens can be helpful to distinguish HSA from other undifferentiated neoplasms.[8,9]

Importantly, the right atrium and auricle is the third most common site for HSA in the dog, and HSA is the most common heart tumor.[10–15] Pericardial effusion, cardiac tamponade, or both are common sequelae to cardiac HSA.[16,17] Twenty-five percent of dogs with splenic HSA also have right atrial HSA.[18] It is not known whether the splenic or atrial lesion is primary or secondary. It seems most likely that right atrial lesions in dogs with splenic HSA are metastatic, because many dogs with right atrial HSA do not have splenic HSA. In addition to the aforementioned metastatic sites, HSA metastasizes to the brain in approximately 15% of cases.[19] HSA generally metastasizes via hematogenous routes (e.g., lungs, liver, brain) or by direct extension via transabdominal implantation via tumor rupture (e.g., omentum, mesentery).[13,18]

HSA tends to be a disease of older dogs and cats with a median age of 9 to 10 years. However, reports exist of extremely young dogs and cats with this disease (5 to months to a few years of age).[20–23] German shepherd dogs are the most common breed of dog diagnosed with HSA.[10] Other large breed dogs, such as golden retrievers and Labrador retrievers, may also be over-represented. In cats, the most common breed is the domestic shorthair (DSH).[24–26] HSA appears to be less common in cats (< 0.5% of all tumors) than dogs, with the most common primary tumor sites including spleen, liver, or mesentery.[27–29] Intra-abdominal HSA in the cat appears to be a highly malignant neoplasm, similar to that in dogs; metastatic sites commonly include lungs, liver, omentum, diaphragm, and occasionally pancreas.[21–26] There does not appear to be an overt gender predisposition for HSA in dogs or cats; however, some reports suggest that male dogs are redisposed.[10,12,20,23]

The cause of HSA in dogs and cats is unknown. Exposure to toxins such as vinyl chloride, dioxides, radiation, and arsenicals have been reported in humans to be associated with HSA.[30–32] Radiation exposure in dogs has been implicated as a potential cause of HSA[33]; however, the implanted doses of radiation were high and lengths of time of implantation and subsequent exposure were long in these studies. Interestingly, the ingestion of methylnitrosamines from fish meal by mink has been implicated in the carcinogenesis of HSA.[20] Ultraviolet (UV) light exposure may be a potential cause of HSA in dogs because cutaneous HSAs are commonly seen in dogs with light hair and poor pigmentation (e.g., salukis, whippets, white bulldogs).[34]

184.2 HISTORY AND CLINICAL SIGNS

Due to its cell of origin, HSA can be found in dogs or cats in almost any anatomic locale; therefore the history and clinical signs can vary. At the most extreme, HSA can cause sudden death due to tumor rupture, acute blood loss, or both. At the other end of the spectrum, nonspecific signs such as anorexia, vomiting, and lethargy can be seen in dogs and cats with HSA. It is quite common for HSA patients with intra-abdominal or intrathoracic disease to have a history of weakness, pale mucous membranes, or collapse (or a combination of these signs). Other potential historical abnormalities that may be noted by owners are abdominal distension, dyspnea, and weight loss. Episodes with weakness and collapse can last for minutes to hours with recovery from the episode being a common feature. It is surmised that the weakness, pale mucous membranes and collapse are due to acute blood loss, whereas the dramatic recovery is likely due to discontinuation of the acute blood loss, autotransfusion of the blood lost into a body cavity, or both.

In those situations where the heart is involved, the acute blood loss from the HSA can result in pericardial or thoracic effusion (or both), which can result in cardiac tamponade. On physical examination, these dogs may have clinical signs of right heart failure, muffled heart sounds, and arrhythmias.[16,35] The neurologic form of HSA can cause a variety of neurologic signs that include seizures.[19] The cutaneous form of HSA generally causes discrete nonulcerative dermal to subcutaneous masses that are firm, raised, and dark purple to red. When involving the deeper tissues such as muscle, deep fascia, or both, dogs may have a large mass, firmness in the muscle, lameness, or a combination of these signs. Swelling distal to the lesion can be seen with extremely large intra-or intermuscular HSA.

758 759

184.3 DIAGNOSIS AND STAGING

Presumptive diagnosis of HSA can be based on the history, signalment, and physical examination findings. In addition, other diagnostics such as radiography, ultrasound, and fine needle aspiration or paracentesis (or both) are valuable. Serosanguineous effusions associated with HSA generally do not clot and upon cytologic examination only reveal a confirmatory diagnosis in 25% of dogs.[35]

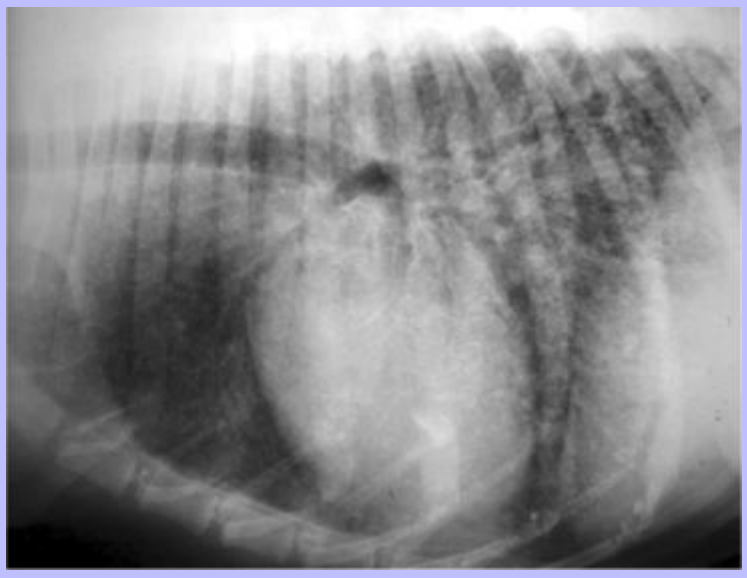
It cannot be overemphasized that the definitive diagnosis of HSA can only be made via biopsy and histopathologic examination (or in the rare instance of the aforementioned cytologic-based diagnosis). After surgical removal, large lesions should be “bread-loaf” sectioned to allow for full fixation by formalin, and then the entire sample submitted whenever possible. In those situations in which the sample and concomitant formalin represent too large a volume for transport to the pathology laboratory, one can either (1) fully fix the bread-loafed specimen overnight, remove the specimen, and submit in formalin-wetted towels to prevent sample drying or (2) submit representative smaller samples from a variety of regions of the lesion. Whenever possible the entire resection should be submitted no matter what type of neoplasia is suspected, because this best allows the pathologist to discern a final diagnosis with delineation of resection margins. If the diagnosis of HSA is suspected and

histopathologic review does not document the presence of HSA, then further consultation with the histopathologist and additional review of submitted tissues may be helpful.

Nondermal HSA is commonly a metastatic neoplasm based on necropsy studies. Because the prognosis (discussed later in this chapter) and potential need for additional therapy is highly dependent on clinical stage, a thorough evaluation for evidence of metastatic disease is highly recommended. Thoracic radiographs with right and left lateral views and ventrodorsal views should be performed for delineation of possible lung metastasis, cardiac involvement, or both with the presence of pericardial effusion. Although many sarcomas with pulmonary metastasis will have a classic nodular or "cannonball appearance," HSA pulmonary metastases can have a military to coalescing miliary pattern as seen in Figure 184-1.[36,37] Radiography was able to detect pulmonary HSA metastasis and cardiac involvement (because of an abnormal silhouette) in 78% and 47% of dogs, respectively.[37] The most accurate diagnostic for cardiac involvement from HSA is echocardiography.[38,39] The value of echocardiography for staging HSA is continuing to be evaluated. Echocardiography is recommended for HSA staging whenever available and financially feasible.

Use of abdominal ultrasound is strongly recommended for additional staging of HSA. It can be a valuable tool for evaluation of a primary intra-abdominal tumor and delineation of the presence of metastatic spread. The echo pattern most commonly seen in dogs with splenic HSA is mixed or nonhomogenous (or both), whereas hepatic metastases generally appear anechoic or hypoechoic.[40] If metastatic spread is felt to be highly likely on ultrasound examination, it must be emphasized that a tissue-based histopathologic or cytopathologic diagnosis (or both) is necessary to prove that metastatic disease is indeed present. Importantly, abnormalities seen on abdominal exploratory for a splenic HSA, such as masses on the liver, omentum, diaphragm, should all be biopsied and evaluated histopathologically. The clinical staging system for HSA is shown in Box 184-1.

Figure 184-1 Lateral chest radiograph of a 6-year-old castrated male golden retriever 52 days after splenectomy for a splenic hemangiosarcoma. The reader should note the non-nodular miliary metastatic pattern.



The most common hematologic finding in dogs with HSA is anemia.[13,20,41] The anemia is generally a regenerative normocytic-normochromic anemia with polychromasia, reticulocytosis, nucleated red blood cells (RBCs), and anisocytosis.[13,20,41] The anemia associated with HSA is generally felt to be due to microangiopathic hemolysis and possibly intracavitary hemorrhage (with subsequent autotransfusion), which results in RBC fragmentation and schistocytosis in canine and human HSA but not feline HSA.[42] Other common hematologic abnormalities in dogs and cats with HSA also include neutrophilic leukocytosis, band neutrophilia, and thrombocytopenia. Significant thrombocytopenia can be seen in approximately one half of dogs with HSA.[43,44] In addition, spontaneous hemorrhage and disseminated intravascular coagulation (DIC) may occur in dogs and cats with HSA, and therefore a coagulogram is strongly recommended prior to the use of invasive diagnostics, surgery, or both.

III = T2 or T3, N0 or N1 or N2, M1

184.4 TREATMENT AND PROGNOSIS

184.4.1 Surgery

Surgery continues to be the gold standard treatment for dogs and cats with HSA. Due to the metastatic propensity of nondermal HSA, this disease should be one that is routinely thought of as having two problems: (1) local tumor control and (2) systemic tumor control. Therefore even though surgery remains the gold standard, it is almost always used in concert with some systemic therapy modality in nondermal HSA because the prognosis for dogs with splenic HSA treated with surgery alone remains poor to grave with a median survival time (MST) of only 19 to 86 days.* The prognosis for cats is also poor. Cats have a MST after splenectomy for splenic HSA of only 20 weeks.[26] Surgery should be used as aggressively as possible for HSA to remove all diseased tissue whenever possible. For example, for dogs with intramuscular HSA, a radical myectomy or amputation would be recommended, whereas with splenic HSA a splenectomy would be the surgical methodology of choice. Due to aforementioned staging concerns, any suspicious lesions (e.g., omentum, diaphragm, liver, lymph nodes) noted at the time of surgery should also be biopsied and histopathologically examined. For dogs undergoing splenectomy for splenic HSA, development of ventricular arrhythmias, thought to be due to hypovolemia, anoxia, and anemia, occurred in approximately one quarter of dogs postoperatively.[47]

Local tumor control is especially problematic for dogs with HSA of the pericardium, right atrium, or both due to anatomic constraints. Exploratory thoracotomy may be performed with removal of the tumor by pericardiectomy for pericardial HSA, as well as the use of staples and hand suturing for right auricular and atrial tumors.[14,16,48] Unfortunately the prognosis for HSA at this anatomic location is also poor to grave, with death being reported within 3 to 5 months (median survival only weeks) after surgery.[14,16] Thoracoscopy appears to be a promising less-invasive diagnostic modality and has also been reported as a methodology for pericardiectomy.[48,49]

Cutaneous HSA without hypodermal invasion is less metastatic than nondermal HSA. The median survival of dogs with dermal only HSA (treated by surgical resection) was 780 days, whereas in dogs with hypodermal or deeper involvement of their cutaneous HSA (or both) have MSTs of 172 and 307 days, respectively.[50] Therefore it appears that hypodermal involvement in canine cutaneous HSA warrants a poorer prognosis and probable need for adjuvant therapy when compared with dermal HSA. Cats with cutaneous HSA treated by surgical excision had a MST of 44 weeks.[26]

184.4.2 Chemotherapy

Hypodermal or deeper canine and feline HSA appears to be routinely metastatic, and therefore adjuvant therapy is considered necessary after surgery. As shown in Box 184-2, doxorubicin-based protocols are most commonly reported. Similar MSTs are noted whether doxorubicin is used adjuvantly as a single agent or in combination with cyclophosphamide (i.e., adriamycin and cyclophosphamide) and vincristine (i.e., vincristine, adriamycin, and cyclophosphamide [VAC]) as shown in Table 184-1.[45,51–53] Because single-agent doxorubicin appears to have similar activity to VAC and AC with less toxicity, doxorubicin may be the therapy of choice for HSA.[45] However, doxorubicin appears to have limited therapeutic benefit. For those dogs with nondermal HSA

receiving five doses of doxorubicin after surgery, negative prognostic factors included (1) younger age, (2) higher grade and degree of anaplasticity and undifferentiation, and (3) incomplete gross tumor removal.[45] Other chemotherapy regimens such as single-agent vincristine and VCM (vincristine, cyclophosphamide, and methotrexate) have been reported in dogs with HSA[13,54]; however, their use is not recommended due to limited therapeutic activity. 760 761

184.4.2.1 **Box • 184-2 Canine Hemangiosarcoma Adjuvant Chemotherapy Protocols**

184.4.2.1.1 **1. A (Adriamycin)**

Doxorubicin IV every 3 weeks for 5 treatments

30 mg/m2 for dogs >10 kg

1 mg/kg for dogs ≤10 kg OR cats

Note: Pretreatment CBC/platelet counts required.

Need >3000 neutrophils and >75,000 platelets to treat

Nadir CBC/Plt at 7–10 days

184.4.2.1.2 **2. AC (Adriamycin and Cyclophosphamide)**

Day 1—Doxorubicin (see "A" protocol) and 100–150 mg/m2 cyclophosphamide IV

Can substitute IV Cytoxan with Oral at 50 mg/m2 on days 3, 4, 5, 6

Day 22—Repeat cycle for 4–6 total cycles

Note: Antibiotics may be required due to significant myelosuppression.

184.4.2.1.3 **3. VAC (Vincristine, Adriamycin, and Cyclophosphamide)**

Day 1—Doxorubicin (see "A" protocol) and cyclophos phamide 100–200 mg/m2 IV

Day 8—Vincristine at 0.75 mg/m2

Day 15—Vincristine at 0.75 mg/m2

Day 22—Repeat cycle for 4–6 total cycles

Note: Clinician should stop chemotherapy for 1 week if any pretreatment CBC has <3000 neutrophils. Antibiotics may be required prophylactically and/or therapeutically because this protocol is extremely myelosuppressive.

Table • 184-1 Survival Times for Canine Hemangiosarcoma

TREATMENT	MEDIAN SURVIVAL IN DAYS	REFERENCES
Splenectomy	19–86	1, 5, 13, 45
Splenectomy and MBVacc +/–VMC	91–117	13
Splenectomy and VAC	145	51
Splenectomy and AC	141–179	53, 62
Splenectomy and AC and L-MTP-PE	273	55
Complete Surgery and A	172	45
Incomplete Surgery and A	60	45

Dogs with earlier-stage hypodermal or deeper HSA treated with surgery and chemotherapy appear to have a better prognosis compared with dogs with more advanced stage disease based on multiple studies.[13,55,56] When taken in concert with the aforementioned negative prognostic factor of incomplete tumor resection,[45] it appears that the use of adjuvant chemotherapy is most beneficial in dogs with earlier-stage, nonruptured, and completely resected HSA. It therefore cannot be overstated that preoperative staging is imperative for preoperative prognosis in dogs suspected of having HSA.

184.4.3 Immunotherapy and Biologic Therapy

Relatively few studies have been published investigating the therapeutic efficacy of biologic response modifiers in canine HSA. Modest improvement in survival was noted for dogs receiving a killed bacterial vaccine after splenectomy compared with splenectomy alone.[13] Macrophage-activating agents such as L-MTP-PE (liposome-encapsulated muramyl tripeptide phosphatidylethanolamine) appear to have tumoricidal activity against a variety of neoplasms.[57–59] In a surgical adjuvant-chemotherapy canine HSA study, L-MTP-PE significantly prolonged disease-free survival and overall survival[55]; unfortunately, this compound is presently not commercially available.

Based on the cell of origin, antiangiogenic approaches are thereby logical anticancer approaches to HSA. Minocycline is an antibiotic with antiangiogenic activity.[60,61] Dogs with HSA were treated with surgery, AC (i.e., doxorubicin and cyclophosphamide), and minocycline; however, no statistically significant change in survival was noted in comparison to historical controls.[53,56] Although these results are discouraging, additional investigations using novel rationally targeted therapies for HSA are desperately needed and encouraged.

184.4.4 Radiation
